The white blood cell count is increased and may reach 20,000 or 30,000 cells per cu mm. Blood smears are apt to show a relative increase in the percentage of polymorphonuclear and large mononuclear cells Examination of the urine may show a slight albuminuria, and hyaline casts may be found in the sediment. A reaction for glucose and acetone is noted in most cases. There is no marked increase in the spinal fluid pressure, but the level ordinarily will be above the average figure. The fluid is consistently clear, though tests may show a slight increase in the amount of protein The cell count usually is within normal limits, more than 100 cells are encountered rarely, if there is an increase, the cells are predominantly of the mononuclear type

If a patient is known to have been bitten by a rabid animal and the symptomatology is characteristic, there is little difficulty in making a correct clinical diagnosis However, in some cases it is impossible to obtain a history of exposure due largely to the failure of a patient or his relatives to recollect a minor wound produced by an apparently healthy dog In such cases, unless the clinical course is typical, the diagnosis may be missed

At times the clinical course of rabies may be very similar to that of poliomyelitis Other viral and rickettsial agents that produce encephalitis or encephalomyelitis must be considered in the differential diagnosis Tetanus may develop following bites by animals, but the incubation period is shorter than that of

rabies, ordinarily from 6 to 14 days. Trismus, though a very constant symptom of tetanus, is rarely present in rabies, and the muscular spasticity in tetanus is constant and general, while in rabies it is intermittent and affects chiefly the muscles of the throat. Where there has been a definite history of dog-bite or other exposure to rabies, it is not uncommon to encounter rabies hysteria In such cases, a patient ordinarily attempts to emulate convulsive seizures. Patients receiving rabies vaccine treatment may develop paralysis attributable to a sensitization caused by the rabbit brain material in the vaccine This paralysis may simulate paralytic rabies and may produce symptoms referable to cranial nerves, such as difficulty in swallowing, paralysis of the masseter muscles and unilateral or bilateral facial paralysis Encephalitis without paralysis may be caused by the vaccine treatment, and in such cases the disease begins with high fever and headache which may be followed by convulsions and coma

The nonfatal or so-called abortive type of rabies described by Koch is uniformly a paralytic disease. On clinical grounds it is impossible to differentiate treatment paralysis occurring as the result of rabies vaccination from paralytic rabies Failure to demonstrate rabies virus in the brain at necropsy is considered evidence in favor of a diagnosis of paralysis due to the vaccine In dealing with animals, however, isolation of the virus becomes increasingly difficult the longer an animal lives after the onset of the disease, and when death is delayed for a week or more it may be impossible to isolate the virus Histologic examination of the brain and the spinal cord in fatal cases of paralysis caused by vaccination will not aid in differentiating the condition from paralytic rabies Furthermore, the problem of differentiating the two conditions cannot be solved by immunologic tests, since the vaccine treatment as well as the disease results in the development of specific antibodies to rabies virus. The concept that rabies in man is always fatal is based on the knowledge that rabies virus has not been isolated from a human being that developed encephalitis and recovered However, the laboratory diagnosis of rabies depends on the isolation of the virus from the saliva, and the testing of saliva for rabies virus has been done so rarely that there are only a few records of isolation of the virus from this source. Of course, a negative saliva test does not rule out rabies infection, since the virus may fail to become established in the salivary glands It is essential to inoculate rabies virus into the brain of the common laboratory animals in order to be certain of producing a characteristic fatal infection. Before the discovery of modern antibiotics, such as penicillin and streptomycin, saliva specimens when introduced into the brain of such animals invariably produced bacterial sepsis Inoculation of the animals by the peripheral route was the only means of testing for the virus in saliva, and the low infection rate and the long incubation period of the disease in animals inoculated by this route made this a tedious and uncertain method of diagnosis It is possible to test saliva specimens for rabies virus by intracerebral inoculation into mice if this material is diluted in physiologic salt solution containing penicillin and streptomycin. This saliva test should be done on all patients that become ill after animal bite and in cases of encephalitis or encephalomyelitis of unknown etiology.

PATHOLOGIC PICTURE

There is slight to moderate ... as shown by flattening of the cerebral convolutions and partial obliteration of the sulci On section, the cut surface of the brain and the spinal cord has a pink cast. Ordinarily, this is more marked in the thalamus, the medulla and the cervical spinal cord When the site of the bite is located on one of the extremities, the cut surface of the spinal cord may show unilateral, pinkish-gray discoloration and obliteration of the normal markings. This lesion, when present, is most marked in the posterior horn. The mucosa of the trachea and the bronchi is congested. The cervical lymph nodes may be slightly enlarged. The thymus may be enlarged and edematous The mucous membrane of the gastro-intestinal ...

eninges

ble de-

gree of hyperemia and slight perivascular infiltration with mononuclear cells may be seen. The cerebral and the cerebellar cortices show general hyperemia and acute neuronal degeneration The white matter exhibits variable demyelinization and degeneration of axis cylinders In the midbrain, the basal ganglia and the pons, the neuronal degeneration generally is severe and is associated with marked hyperemia Small perivascular hemorrhages, most noticeable in the thalamus and subependymal neuroglial tissue, are seen frequently Neuronal degeneration is especially

tion The medulla uniformly presents the maximum pathologic alteration The cranial nerve nuclei exhibit marked neuronal degeneration, and the infiltration by mononuclear cells is proportionally greater than elsewhere The spinal cord shows hyperemia and perivascular infiltration, which are especially marked in the cervical portion at the decussation of the motor tracts The neuronal degeneration is apt to be extensive in the posterior horns When the site of the bite is located on one of the extremeties, the corre-

extensive degeneration of axons and myelin sheaths The contiguity of the axon is disrupted so that it appears beaded, and the myelin sheath is vacuolated The dorsal root ganglia from the same region show marked neuronal degeneration and moderate to marked mononuclear cell infiltration In general, the leukocytic infiltration is largely perivascular, but clusters of mononuclear cells are found about degenerating neurons, especially in the cranial nerve nuclei The leukocytes found in the neuroglial tissue are, for the most part, of the small and the large mononuclear types, but in some cases polymorphonuclear cells are present There is apt to be a slight diffuse mononuclear cell infiltration of the interstitial tissue of the pons, the medulla and the cervical spinal cord, varying in proportion to the degree of neuronophagia Cellular infiltration may be very scanty when a patient dies soon after the onset of the disease and is proportionally greater the longer the duration of the disease The neuroglial cells of the substantia gelatinosa about the central canal show a variable degree of proliferation; this is especially evident in the spinal cord The neuroglia about degenerating neurons become more prominent than usual, and, though this may result from an increase in size, it is suggestive of proliferation. The oligodendroglia throughout the brain show swelling, a manifestation of the moderate cerebral edema which is present in all cases Most of the neurons of the central nervous system show some pathologic alteration The main change consists of pyknosis of the nucleus and ballooning of the cytoplasm The Nissl sub-

coagulative necrosis, while others exhibit fragmentation of the cytoplasm and general loss of cellular detail

The inclusion bodies which can be demonstrated in the neurons of the majority of cases of rabies generally are referred to as Negri bodies These structures when present

defined, spherical, oval or elongated eosinophilic bodies, ordinarily 2 to 10 microns in diameter Several inclusion bodies, usually of variable size, may be present in one neuron and are found most often in the cytoplasm between the nucleus and the dendritic prolongations of the cell They also may be found in the first part of the dendrite and in such instances are elongated The characteristic inclusion body contains an inner structure of basophilic granules, which vary from 0 2 to 0 5 microns in diameter and are surrounded by a clear zone in preparations stained by Wolbach's modification of Giemsa's stain. Large inclusion bodies have a central granule and one or more concentric layers of these inner bodies, separated by a finely granular ground substance or matrix

similarity to inclusion bodies found in other diseases Characteristic inclusion bodies of rabies are apt to be more abundant in Ammon's horn of the hippocampus than elsewhere in the nervous system but may be found in large numbers in the pyramidal cell layer of the cerebral cortex, the Purkinje cell layer of the cerebellum and in the large neu-

rabies, ordinarily from 6 to 14 days. Trismus, though a very constant symptom of tetanus, is rarely present in rabies, and the muscular spasticity in tetanus is constant and general, while in rabies it is intermittent and affects chiefly the muscles of the throat. Where there has been a definite history of dog-bite or other exposure to rabies, it is not uncommon to encounter rabies hysteria. In such cases, a patient ordinarily attempts to emulate convulsive seizures. Patients receiving rabies vaccine treatment may develop paralysis attributable to a sensitization caused by the rabbit brain material in the vaccine. This paralysis may simulate paralytic rabies and may produce symptoms referable to cranial nerves, such as difficulty in swallowing, paralysis of the masseter muscles and unilateral or bilateral facial paralysis. Encephalitis without paralysis may be caused by the vaccine treatment, and in such cases the disease begins with high fever and headache which may be followed by convulsions and coma.

The nonfatal or so-called abortive type of rabies described by Koch is uniformly a paralytic disease. On clinical grounds it is impossible to differentiate treatment paralysis occurring as the result of rabies vaccination from paralytic rabies. Failure to demonstrate rabies virus in the brain at necropsy is considered evidence in favor of a diagnosis of paralysis due to the vaccine. In dealing with animals, however, isolation of the virus becomes increasingly difficult the longer an animal lives after the onset of the disease, and when death is delayed for a week or more it may be impossible to isolate the virus. Histologic examination of the brain and the spinal cord in fatal cases of paralysis caused by vaccination will not aid in differentiating the condition from paralytic rabies. Furthermore, the problem of differentiating the two conditions cannot be solved by immunologic tests, since the vaccine treatment as well as the disease results in the development of specific antibodies to rabies virus. The concept that rabies in man is always fatal is based on the knowledge that rabies virus has not been isolated from a human being that developed

so rarely that there are only a few records of isolation of the virus from this source. Of course, a negative saliva test does not rule out rabies infection, since the virus may fail to become established in the salivary glands. It is essential to inoculate rabies virus into the brain of the common laboratory animals in order to be certain of producing a characteristic fatal infection. Before the discovery of modern antibiotics, such as penicillin and streptomycin, saliva specimens when introduced into the brain of such animals invariably produced bacterial sepsis. Inoculation of the animals by the peripheral route was the only means of testing for the virus in saliva, and the low infection rate and the long incubation period of the disease in animals inoculated by this route made this a tedious and uncertain method of diagnosis. It is possible to test saliva specimens for rabies virus by intracerebral inoculation into mice if this material is diluted in physiologic salt solution containing penicillin and streptomycin. This saliva test should be done on all patients that become ill after animal bite and in cases of encephalitis or encephalomyelitis of unknown etiology.

PATHOLOGIC PICTURE

There are no gross abnormalities which can be regarded as diagnostic of rabies. The surface of the brain and the spinal cord usually exhibits a pink or red discoloration caused by marked engorgement of the blood vessels. There is slight to moderate cerebral edema as shown by flattening of the cerebral convolutions and partial obliteration of the sulci. On section, the cut surface of the brain and the spinal cord has a pink cast. Ordinarily, this is more marked in the thalamus, the medulla and the cervical spinal cord. When the site of the bite is located on one of the extremities, the cut surface of the spinal cord may show unilateral, pinkish-gray discoloration and obliteration of the normal markings. This lesion, when present, is most marked in the posterior horn. The mucosa of the trachea and the bronchi is congested. The cervical lymph nodes may be slightly enlarged. The thymus may be enlarged and edematous. The mucous membrane of the gastro-intestinal tract is congested.

When examined histologically the meninges usually appear to be normal. A variable de-

ity rate of 90 to 100 per cent is obtained if the natural virus is present in high titer in the infected tissue When a 10^{-2} dilution of the same virus preparation is inoculated into dogs in the volume and the manner described, the mortality rate is not reduced markedly, but the mean incubation period may be increased to 40 to 50 days The same type of natural virus, when titrated in dogs by the intracerebral method, may show an LD_{50} of $0.5\ cc \times 10^{-3.3}$ In this instance, the incubation period may be as short as 8 days, but, with rare exceptions, the disease will develop from 10 to 20 days after inoculation, however, a latent period of from 2 to 3 months may be observed The mortality rate following intradermal or subcutaneous inoculation is less than 25 per cent

The signs of rabies in dogs infected by peripheral inoculation are similar to those observed in man For practical purposes, rabies in dogs is classified as furious or dumb type, depending upon the signs shown In the former type, the excitation phase is prolonged, while in the latter, the paralytic phase develops early Most infected dogs show some manifestation of both types, that is, a short excitation phase characterized by restlessness, nervousness and viciousness, followed rapidly by depression and paralysis The incidence of the two types of the disease is not constant and depends on the character of the natural virus Sudden death of dogs from rabies, without appreciable signs of illness, is not uncommon Dogs that develop the predominantly excited type of rabies have a mortality rate of nearly 100 per cent, and the disease usually terminates in death within 3 or 5 days In an exceptional case the dog may live for 2 or 3 weeks from the onset of illness The behavior observed during the prodromal phase of the disease in dogs is of two types most infected animals become increasingly apprehensive and nervous, while others seek solitude and become increasingly apathetic In the former type, a dog may appear unusually friendly, which is probably a manifestation of fear This is the most dangerous phase of the disease as the dog is very excitable and will bite at the slightest provocation A rabid dog is more likely to bite a stranger than its master during the early stage of the disease, but with the onset of the acute excitement phase it may show no recognition of its master and exhibits only an insane desire to attack and bite. The symptom of hydrophobia does not occur in canine rabies, but difficulty in swallowing is common Partial or complete paralysis of the muscles of phonation occurs in most rabid dogs as shown by a characteristic change in their bark or growl or by inability to make any sound This may be the reason why rabid animals so often attack without warning The tendency of rabid dogs to eat dirt, straw, bedding and wood is well known If caged, the animal may break off its teeth in attempts to free itself During the prodromal phase, the physical signs include fever, a decrease or loss of the corneal reflex, decreased sensation to painful stimuli, dilation of the pupils, and an increase in muscle tone which gives the animal an alert appearance As the disease progresses, a dog may be unable to close its eyes completely, and the eyes take on a glazed appearance, resulting from dryness of the corneae An animal may show twitching of muscles, a general muscular tremor, in-co-ordination and convulsive seizures If a dog does not die at this stage, progressive paralysis and coma precede death Dogs infected experimentally by inoculation of virus into the masseter muscles ordinarily develop paralysis of these muscles early, which is spastic at first, making it difficult for the animals to open their jaws after biting Dogs infected by inoculation of the virus into the hind leg muscles usually develop spastic paralysis of the hind legs before other muscles are involved, and paralysis of the jaw occurs late in the course of the disease, if at all The initial febrile period may last 1 or 2 days, and then the temperature drops to normal or subnormal levels A second febrile period is uncommon, but some animals develop a high terminal fever

Transmission of rabies among dogs and related canines depends on the ability of the virus to reach and to multiply in the salivary glands The virus may be present also in the lacrimal glands, the pancreas, the kidney and breast tissue The adrenal glands are likely to contain virus, but cellular degeneration is confined to the medulla and is evidently a part of the general involvement of nervous tissue The virus has not been demonstrated with certainty in the blood, the spleen, the liver,

rons of the basal ganglia and the cranial nerve nuclei They may be found also in neurons of the spinal cord, the dorsal root ganglia, the ganglionic cell layer of the retina, and ganglia of the sympathetic nervous system Negri believed that the intracytoplasmic inclusion bodies of rabies represented one stage in the development of a protozoan parasite Subsequent studies of the inclusion bodies of rabies, as well as those found in other viral diseases, indicate that, while they may contain infective units of the virus, they are composed largely of a matrix derived from the cytoplasm of degenerating cells The absence of thymonucleic acid from the Negri body as shown by the Fuelgen stain conforms with the characteristics of other inclusion bodies due to infection with a virus The matrix contains considerable lipid material as shown by selective staining methods

Neurons of ganglia of the sympathetic nervous system and the dorsal root ganglia of the spinal cord show degenerative changes similar to those of the brain Marked ballooning and vacuolation of the cytoplasm may be present. The interstitial tissue of the ganglia may show moderate to extensive infiltration of mononuclear cells The degenerating neurons are surrounded by large cuboidal cells which appear to be derived from cells of the sheath of Schwann The peripheral nerves, particularly those related to the site of the bite, show coalescence of neurofibrillae and fragmentation of axis cylinders, vacuolation of the myelin sheath and a variable degree of mononuclear cell infiltration in the perineural lymphatics

If the salivary glands contain virus, there

be markedly distended with amorphous ma-

ach mucosa may show acute degeneration. Acute degeneration of the acinar epithelium of the pancreas and the epithelial cells of the renal tubules may be found in some cases of rabies Acute degeneration of the medullary cells of the adrenal gland can be correlated with the presence of the virus and,

the

ract

may show congestion and edema of the mucosa, and the neurons of the sympathetic plexuses may show degenerative changes sim-

Focal degeneration of the striated muscle has been observed in the tongue

In the absence of specific inclusion bodies in the neurons of the central nervous system, a definite diagnosis of rabies cannot be made with certainty on the basis of the pathologic picture, because the lesions produced by rabies virus are similar to those found in other viral encephalitides

EXPERIMENTAL INFECTION, HOST RANGE

The natural variety of rabies virus as obtained from dogs is pathogenic for all mammals. Injection of the virus into the peritoneal cavity, skin, subcutaneous tissue, muscle, or nervous tissue, in that order, is increasingly efficacious in producing encephalitis. With rare exceptions, intracerebral inoculation of the natural virus obtained from dogs will

encephalitis Intranasal inoculation is almost as effective as intramuscular inoculation in producing the disease Young chickens ordinarily develop a fatal paralytic disease following intracerebral inoculation, but recovery from the disease produced in this way is relatively frequent in mature chickens

The domestic dog is the principal source of human infection, and the nature of the canine street virus can be determined best by study of the disease in this host. A normal dog bitten by a rabid animal may develop rabies within 10 days, or it may show no signs of the disease until several months later. The usual incubation period varies from 21 to 60 days Following inoculation with the natural virus obtained from infected dog salivary-gland tissue, the incubation period depends to a large degree on the amount of active virus introduced. For example, dogs inoculated in each masseter muscle with 0.06 cc of the supernate of a 10 per cent suspension of infected salivary-gland tissue ordinarily develop rabies within 15 or 25 days, with a mean latent period of from 19 to 21 days A mortal-

animals, as well as dogs and large domestic animals such as sheep, horses, calves and goats However, it appears to be unable to produce disease in human beings when given by subcutaneous inoculation A 100 per cent mortality can be obtained in guinea pigs and mice by intramuscular inoculation of large doses of Pasteur rabbit brain-fixed virus Rabies virus adapted to mice by intracerebral passage has an LD_{50} of about 0 03 cc $\times 10^{-7}$ when titrated intracerebrally in mice Such strains of rabies virus have the same pathogenicity range for laboratory animals and dogs as does the rabbit brain-fixed virus. The capacity of the natural virus to form Negri bodies ordinarily is lost following 25 serial intracerebral passages in mice. Some varieties of rabies virus obtained from animals infected in nature are more pathogenic for infant mice than for mature mice. The Flury LEP virus (<50 passages in eggs), when inoculated intramuscularly is pathogenic for mice, hamsters and guinea pigs but not for rabbits and dogs When inoculated intracerebrally it is pathogenic for mice, guinea pigs, hamsters, dogs and monkeys but only slightly so for rabbits The Flury HEP virus (>180 passages in eggs) when inoculated intramuscularly is not pathogenic for mice, guinea pigs, hamsters, cattle, dogs and man When inoculated intracerebrally it is pathogenic for infant mice and monkeys, slightly pathogenic for guinea pigs and hamsters but not for mice, rabbits and dogs (Koprowski et al , 1954a)

Rabies virus can be cultivated in the developing chick embryo. Infection is obtained by chorio-allantoic-membrane inoculation (Kligler and Bernkopf, 1938) and by allantoic sac or yolk-sac inoculation of 7-day-old embryos (Koprowski and Cox, 1948a) The infected embryos are smaller than normal when harvested at the time of peak multiplication of the virus on the 9th day after inoculation, but the embryos seldom die until hatching time, i e , 14 days after inoculation Infection of 1-day-old chick embryos by yolk-sac inoculation results in death of the embryos in 4 to 5 days (Yoshino et al , 1956).

Rabies virus may be cultivated in Maitland-type tissue cultures. Both street rabies virus of dog salivary gland origin and rabbit brain-fixed rabies virus may be cultivated in series in hamster kidney tissue culture (Kissling, 1958).

ETIOLOGY

The diameter of rabies virus has been estimated to be 100 to 150 mμ (Galloway and Elford, 1936) and, as is the case with other large viruses, the agent is not readily filterable It will pass through diatomaceous earth and unglazed porcelain filters which hold back common bacteria but is not readily filterable through Seitz EK pads

Resistance of the virus to various physical and chemical agents depends on the source of the infected material and the method of its preparation. In testing the survival of the virus at various temperatures, one must be cognizant of certain factors, such as the original infectivity of tissues as determined by titration, the percentage and the type of tissue which contains the virus, and the diluent used in the preparation of the material to be tested Infected brain or salivary-gland tissue are the best sources of virus The virus, when infected tissues are stored in undiluted neutral glycerol, retains its infectivity for several weeks at room temperature or for several months at refrigerator temperature. The infectivity of tissues exposed to the air at room temperature is lost in 1 or 2 weeks, depending on the prevailing temperature and relative humidity, but at refrigerator temperature the virus may remain active for several weeks and at subfreezing temperatures for 1 or more years In order to study the nature of the virus and its response to physical and chemical agents, it must be liberated from cells by grinding Intracellular enzymes are liberated with the virus which may have an unfavorable effect on its activity, while certain other substances freed from the cells appear to have a protective effect. In dilutions containing less than 0 1 per cent tissue extract, the virus deteriorates rapidly unless normal serum, or bovalbumin fraction V, is added to the diluent Physiologic saline solution is preferable to distilled water for preparing dilutions of infected tissue, as the latter causes precipitation of protein in cell-free supernates, thus making it difficult to maintain a uniform sus-

the lymph nodes or the muscle of animals infected with the natural virus. The virus is demonstrable in the central nervous system of nearly all animals that die of rabies. When the disease is of long duration, autosterilization may take place The medulla and the thalamus usually contain the greatest concentration of virus. The submaxillary salivary glands are the best source of virus from tissue other than the nervous system and may contain more virus per gram of tissue than the brain The appearance of virus in the saliva coincides with the initial febrile response to infection. Dogs infected by intramuscular inoculation of rabies street virus sometimes develop paralytic rabies and recover. There is no record of isolation of rabies virus from the saliva of a naturally infected dog that eventually recovered

In young hamsters, intramuscular inoculation of the natural virus as derived from infected salivary gland tissue reproduces the disease almost as regularly as intracerebral inoculation (Koprowski, 1949) A 100 per cent mortality can be obtained in guinea pigs inoculated intramuscularly with the virus, but this animal is less susceptible than the hamster when the virus is titrated, using this route of inoculation. White mice, white rats and rabbits have a lower mortality rate than guinea pigs when street rabies virus is given by intramuscular inoculation, and development of paralysis followed by recovery is not uncommon in these animals.

The ability of the virus to invade salivary glands varies with different strains and different species of host Tropism of virus for the salivary glands is markedly reduced by a few serial, intracerebral passages in mice The virus as found in dogs appears to be a highly neurotropic variant of the natural virus. The virus found in vampire bats is less neurotropic, as shown by the development of an asymptomatic salivary gland infection in some bats.

In summary, the canine street-virus rabies is characterized by a long and extremely variable incubation period, a prolonged excitement state associated with irritability and viciousness, and a rather constant production of Negri bodies. In a variable but high percentage of cases, the virus is able to reach the salivary glands and be excreted in the saliva The natural virus may be altered by rapid passage in the canine host as shown by the character of the disease produced, i e, by increased speed of multiplication in the brain, more general distribution of virus in this organ, and less tropism for the salivary glands This undoubtedly acts as a check on the spread of rabies, since animals infected with highly neurotropic strains of the virus uniformly develop a paralytic type of disease and do not propagate it by bite

The term "fixed virus" has been applied to strains of the agent that have been propagated by serial intracerebral passage in some experimental animal, usually the rabbit, in which the incubation period has become short and constant. Rabies caused by fixed virus is characterized by an incubation period of 4 to 6 days following intracerebral inoculation, absence of Negri bodies in the brain, wide dissemination of the virus in the central nervous system with consequent high titer, and a rapidly progressing, paralytic disease Such strains have lost to some degree their ability to migrate along nerves and apparently are unable to multiply in the salivary glands

The variety of fixed virus most widely used for human vaccination is the Pasteur strain, which has been maintained by serial passage in rabbits since its isolation in 1882 (Pasteur, 1885) Most of its substrains, which are available have been through 2,000 or more passages in rabbits The several substrains of the Pasteur strain are not identical in their characteristics The incubation period, the antigen coverage and the ability to invade the central nervous system following peripheral inoculation, differ from strain to strain The method of subpassage in some laboratories evidently has led to the loss of certain characters Titration of fixed virus by the intracerebral route of inoculation shows that the incubation period varies inversely in proportion to the amount of virus given, with a range of 4 to 12 days Incubation periods of 3 to 6 weeks may be observed following intracerebral inoculation of mice with mixtures of rabies hyperimmune serum and fixed virus Subpassage of fixed virus strains obtained by this method indicates that the virus has been altered, probably as the result of elimination of certain characters. The Pasteur strain of fixed virus, when given by intracerebral inoculation, is highly pathogenic for all laboratory

Flury virus in chicks was to eliminate the virus type that could multiply in the salivary glands. The virus was routinely passed during the early phase of multiplication, before the onset of signs of disease in the avian host, and this may have been a factor in the selection of the final virus type. There is a danger in assuming that a certain number of chick embryo passages achieves some definite change in a virus, making it safe for use in a vaccine. This is also true for selection on the basis of pathogenicity for mice when inoculated intracerebrally. The natural virus as derived from Mustelidae is apt to have a greater pathogenicity for infant than for adult mice when inoculated intracerebrally. As shown in studies of the Pasteur strain (Wright and Habel, 1948), the antigenicity of the virus may be altered by subpassage in the rabbit. Vaccines produced from some varieties of this strain do not immunize against other varieties of the same virus. The important thing is whether the vaccine produces protection against the natural virus. This was the basis for the selection of the dog salivary gland virus for testing the immunity of dogs following vaccination. The Flury HEP virus produces immunity in mice to street virus under conditions where immunity is not recognized by challenge with brain-fixed strains.

The site of multiplication of non-neurotropic varieties of rabies virus in the mammalian host is not known. It may be that non-neurotropic variants circulate in the blood stream but cannot be demonstrated because they do not produce encephalitis in the mouse when inoculated intracerebrally. It is not certain whether the virus invades the axonal portion of a nerve tract and follows this to the brain. It may reach the brain via the perineural lymphatics. There is pathologic evidence that the virus produces cytopathology in the lymph nodes, the thymus, the salivary glands, the pancreas and the kidneys. Perhaps the virus may be able to multiply in certain types of muscle tissue. The possibility of a viremic phase in the infection with the natural virus has not been ruled out. Viremia does occur in chick embryos infected with Flury LEP virus (Koprowski and Cox, 1948b).

For details of serologic and immunologic tests the reader is referred to Johnson (1956) and Habel (1954). For the neutralization test, it is preferable to use a standard virus against constant amounts of which 10-fold or half-log dilutions of serum are tested. Testing of undiluted serum may result in nonspecific neutralization of the virus. Immune serum may be prepared by immunization of guinea pigs or hamsters. An initial intramuscular injection of the Flury HEP virus will produce immunity to rabies so that an injection of salivary gland street rabies virus may be given later to obtain a wider antigen coverage. The neutralization test is of value for the identification of unknown strains of rabies virus, particularly those modified by serial passage in laboratory animals or those derived from unusual natural sources.

The immunizing potency of rabies vaccine can be estimated by parallel intracerebral titrations of brain-fixed virus in vaccinated and unvaccinated mice (Webster, 1936, 1939). Rabies vaccines marketed in the United States must be tested for immunizing potency (Habel, 1954; Kaplan, 1954). The antigenic value of the killed-virus vaccine is determined by finding the amount of vaccine required to immunize mice against a standard dose of brain-fixed virus given by intracerebral inoculation. The Flury strain live virus vaccine is tested for potency in guinea pigs. The animals are vaccinated with a single intramuscular inoculation of vaccine, and 3 weeks later the vaccinated animals and the control animals are challenged by intramuscular inoculation with street rabies virus of dog salivary gland origin (Koprowski, 1954a). Mice inoculated intracerebrally with the Flury HEP virus will be immune to subsequent intracerebral inoculation of street virus. This is a convenient method for the identification of rabies virus.

DIAGNOSIS

History of exposure, clinical symptoms and signs, and outcome of an illness often play an important part in the diagnosis of rabies in man and lower animals. The development of specific diagnostic methods for determining whether or not animals have rabies was necessitated by the frequency with which human beings are bitten, especially by dogs which in most instances do not have rabies. If a biting dog fails to develop signs of rabies or to

pension of the virus A large proportion of active virus is found in the sediment following centrifugation of macerated tissue, as shown by regrinding the sedimented tissue and titrating the supernate For routine inoculation, it is preferable to use the supernate, as the suspension of tissue may quickly kill experimental animals when injected into the brain By intraperitoneal or intramuscular injection, a tissue suspension is more infectious than the supernate. Physiologic phosphate-saline, at pH 7 4 to 9, containing at least 2 per cent inactivated normal guinea pig or hamster serum, or 0 75 per cent bovalbumin fraction V, is a satisfactory diluent for studies of rabies virus, there is no significant loss of infectivity in the higher dilutions over a period of a few hours at room temperature or 24 hours at 4° C When exposed to a temperature of from 54° to 56° C, aqueous suspensions of virus are inactivated in an hour or less The best method of preserving the virus is through desiccation while in the frozen state followed by storage at 4° C, under such conditions it may remain infective for many years Dried virus is less sensitive to heat and may prove to be infective after 24 hours' exposure to a temperature of from 54° to 56° C. Repeated freezing and thawing of virus suspensions results in loss of infectivity Variation in subfreezing temperature has a harmful effect on the virus If a standard virus is to be used, it should be stored in pyrex glass ampules, sealed, frozen rapidly and kept in a dry-ice chest Dessicated specimens of rabies virus should not be sealed in vacuum, because there is danger of release of the virus when the ampule is opened Nitrogen gas should be introduced to atmospheric pressure before the ampules are sealed

Rabies virus, as obtained in serum-saline suspensions of infected tissue, may be concentrated and purified to some degree by the common methods of selective precipitation of serum proteins, namely, fractional precipitation with ammonium sulfate and iso-electric precipitation, it is found in the globulin-type fraction Cox et al (1947) reported purification and concentration of rabies virus by means of alcohol precipitation

Rabies virus is rapidly destroyed by sunlight or by ultraviolet irradiation It is readily inactivated by formalin, bichloride of mercury, and strong acids and bases. The virus is moderately resistant to ether and chloroform and very resistant to phenol Bacteriostatic concentrations of merthiolate (thiomersal), sulfadiazine and all the common antibiotics do not harm the virus.

Rabies virus as obtained from infected tissue does not consist of a single type of virus but is a mixture of different types of virus particles, some of which are and others of which are not pathogenic for hamsters and guinea pigs when inoculated intracerebrally (Koprowski et al., 1954a). This phenomenon is observed with several of the Group A arthropod-borne viruses. The neurotropic virus type grows out to become the major population in the first brain passage, but the capacity of the virus to multiply in some types of non-nervous tissue is not lost The Flury HEP virus appears to have a high population of virus particles derived from non-nervous tissue Perhaps, the non-neurotropic virus particles multiply more rapidly than the neurotropic when introduced into the tissues of some hosts and either interfere with infection by the latter or produce immunity to the virus before the neurotropic variety completes its incubation period Passage of rabies virus in chick embryos does not readily change its pathogenicity for the mammalian host For example, Bernkopf and Kligler (1940) noted that rabbit brain-fixed virus after 47 passages in chick embryos was still pathogenic for rabbits when inoculated intracerebrally The Flury virus was still pathogenic for rabbits when inoculated intracerebrally after 50 passages in chicks. It is not necessarily the number of passages in the avian host that brings about the change in the pathogenicity of a virus for mammals. The time of harvesting during the growth period of the virus, the physical conditions of the diluent or variation in the dosage of the virus in the inoculum may be the selective factor. For instance, using a large inoculum, western equine virus remains relatively unchanged in neurotropic qualities following prolonged yolk-sac passage in chick embryos, but the virus derived from the terminal infectivity dilutions of embryo tissue, when used as passage inoculum, is the more neurotropic type This can also be accomplished by a single intracerebral passage in mice The first objective of passage of the

bodies are more abundant in infant mice than in mature mice inoculated intracerebrally with some strains of street virus

TREATMENT

There is no specific treatment for rabies once the disease develops Barbiturates are better than morphine for relieving anxiety, because patients exhibit a marked tolerance for morphine, and small doses actually increase the excitement in some cases If sedatives cannot be given by mouth, phenobarbital sodium given by subcutaneous injection is indicated Anesthesia may be used to control convulsive seizures Dehydration develops rapidly in most patients, this may be controlled by intravenous injection of physiologic salt solution.

Human beings exposed to rabies ordinarily know when the exposure occurred and where the virus was deposited. Local treatment of wounds inflicted by rabid animals has been used for centuries, and this is probably the most important means for preventing the disease The object of local treatment is to remove or inactivate virus that may have been deposited in the wound, and thorough washing with a soap or a detergent solution undoubtedly is the best method of accomplishing this The virus cannot be eliminated from tooth puncture wounds by this cleansing treatment Nitric acid cautery is recommended for treatment of puncture wounds

Vaccination with rabies vaccine, following exposure to rabies by animal bite, is recommended by public health authorities throughout the world. When the incubation period is less than 30 days, which can be expected in about 20 per cent of the cases of untreated rabies, the development of immunity from vaccination may not be rapid enough to prevent the onset of the disease Passive immunization by administration of rabies hyperimmune serum is designed to prevent the development of rabies before immunity is obtained from the vaccine treatment Though partial immunity is obtained in the third week after the beginning of the vaccine treatment, it takes at least 30 days to achieve maximum immunity The studies of Hoyt and Gurley, (1938), Habel (1945), and Koprowski et al. (1950) show that rabies hyperimmune serum given 24 hours after exposure is effective in preventing rabies The effectiveness is demonstrated best in animals exposed to street virus Some protection can be obtained if the serum is given as late as 72 hours after exposure but not later (Koprowski et al , 1950) Clinical studies of the combined serum plus vaccine procedure have not shown 100 per cent protection (Shortt et al , 1935, Proca and Bobes, 1940) The most recent report concerning the use of the serum plus vaccine is that of Baltazard and Bahmanyar, (1955) In August, 1954, a rabid wolf invaded an Iranian village and bit 29 persons before it was killed Eighteen persons were bitten on the head, in the past this type of exposure has resulted in a mortality from rabies of about 40 per cent despite vaccine administration. Five of these received only the Semple type vaccine; the other 13 were given one or more injections of rabies hyperimmune serum beginning 32 hours after exposure, followed by the vaccine Those bitten on the body elsewhere than on the head were given only the vaccine There were 4 deaths from rabies 3 of the 5 bitten on the head and given only the vaccine and 1 given the serum plus vaccine The rabies case in the serum plus vaccine series had an incubation period of 22 days, which shows that the incubation period is not always prolonged following the use of rabies hyperimmune serum Although there is no experimental proof that rabies hyperimmune serum given more than 3 days following exposure will have any protective effect, it is recommended in all severe bite exposures on the basis that it may increase the incubation period so that immunity from the vaccine will have time to develop The occasional failure of the combined serum plus vaccine procedure warrants consideration of using a final dose of street virus of salivary gland origin in the immunization of horses in the preparation of the hyperimmune serum, in order to obtain more complete antigen coverage Rabies hyperimmune horse serum is available commercially as a lyophilized product of good keeping quality and should be kept on hand in public health centers in all areas where rabies is endemic The recommended dosage for the refined hyperimmune serum is 0 5 cc per Kg of body weight given by intramuscular injection

die within a period of 7 days, a bitten person

mals infected in nature, or in the brains of laboratory animals inoculated with saliva or infected tissue from such sources The finding of Negri bodies is sufficient for diagnosis of rabies, but when they cannot be found it is necessary to resort to animal inoculation.

Negri bodies are readily demonstrated in impression preparations of brain tissue stained by Sellers' method (1927). Though Negri bodies usually are more abundant and characteristic in Ammon's horn than elsewhere in the brain, it is advisable to make preparations also from the cerebral and the cerebellar cortices. The impression method is of particular value because the anatomic orientation of nerve cells is retained, and there is little distortion and rupture of cells Ammon's horn is exposed by cutting through the cortex over the posterior horn of the lateral ventricle A cross section is removed from the middle of the horn where it bulges up from the floor of the ventricle, and the cut surface is touched to a glass slide Two or 3 impressions are made, and then the slide is flooded with the staining solution Sellers' stain is a modification of van Gieson's stain and is composed of a mixture of basic fuchsin and methylene blue Negri bodies are stained cherry red and stand out in sharp relief, the basophilic inner structure is colored deep blue The cytoplasm of nerve cells is stained blue, nuclei and nucleoli are deep blue; the stroma is rose pink, nerve fibers are colored a deeper pink, neural sheaths are not stained; bacteria, if present, are stained deep blue, and erythrocytes are copper color For the demonstration of Negri bodies in paraffin sections, brain tissue should

bach's modification of Giemsa's stain as described by Mallory (1938).

In human specimens, there is little chance of confusing the inclusion bodies of rabies with those which occur in other diseases. In dog brains, however, inclusion bodies caused by distemper virus may be encountered which are similar to those occurring in rabies The distemper inclusion bodies are pale red, are more refractile than those caused by rabies and have no inner structure. They may be irregular in outline and occur more frequently in the thalamus and the lentiform nuclei than in Ammon's horn Intracytoplasmic inclusions may be found in the brains of mice which do not have rabies. These are small, pink to bright red in color, uniformly round and have no inner structure. There are cytoplasmic secretory granules in the pons which resemble the inclusion bodies caused by some viruses

Diagnosis of rabies by isolation of the virus depends on the injection into animals of saliva taken during the disease or brain tissue obtained at necropsy Since the submaxillary salivary glands are most likely to contain virus, specimens of saliva should be taken from under the tongue. The saliva may be diluted in a serum-saline mixture containing 500 units penicillin and 1 mg streptomycin per cc. and tested by intracerebral inoculation into mice. Brain tissue obtained at necropsy is prepared for inoculation by grinding in a mortar and adding physiologic salt solution to make a 10 per cent suspension The supernatant fluid following centrifugation, is used for inoculation of mice. Antibiotics should be added to a concentration of 500 units of penicillin per cc and 1 mg of streptomycin per cc. Rabies virus as obtained from dogs ordinarily has an incubation period of 6 to 8 days in mice, following intracerebral inoculation The virus as obtained from wild animals is different in that the incubation period is apt to be 12 to 21 days, and the mice have a more prolonged illness. Most of the mice infected with the natural virus by intracerebral inoculation develop flaccid paralysis of the legs which progresses to complete prostration. It is necessary to confirm a diagnosis of rabies in mice by finding Negri bodies or by the serum-virus neutralization test, because several viruses produce a disease picture in this host similar to that of rabies, and nonspecific intracytoplasmic inclusion bodies are common in mice inoculated intracerebrally with pathogenic bacteria or viruses.

Because Negri bodies become more numerous with progression of the disease, it is advisable to hold biting dogs in quaratine Negri bodies can be found in approximately 90 per cent of naturally infected dogs. Negri

tis caused by vaccine is characterized by high fever, delirium, convulsions and coma which may terminate in death Nonfatal cases ordinarily recover without sequelae The studies of Stuart and Krikorian (1928), Rivers et al (1933), Morgan (1947), and Kabat et al (1947) show that brain tissue functions as an organ-specific instead of a species-specific antigen Therefore, paralysis caused by rabies vaccination must be considered as a specific sensitization to brain material Reactions of the paralytic type are most apt to occur in persons who have had a previous course of rabies vaccine (Horack, 1939, Sellers, 1947). McKendrick (1940) recorded 55 cases of vaccine paralysis, with 14 deaths, among 488,795 persons given Semple type vaccine

The Flury LEP live-virus vaccine has been shown to be superior to Semple type killed-virus vaccine for the immunization of dogs (Koprowski and Black, 1952, Tierkel et al, 1953) The Flury LEP virus has been used on a large scale in dogs, and there is no evidence of paralytic reactions from sensitization to the nervous tissue in the chick embryo This experience with the Flury LEP virus in animals and the development of the Flury HEP virus which has very little pathogenicity for mammals has prompted investigation of the use of Flury HEP virus for immunization of man Inoculation of mice, guinea pigs, dogs and cattle with Flury HEP virus produces immunity to infection with street virus The protection ratio for calves was the same whether 3 cc or 15 cc of the Flury HEP vaccine virus was given by intramuscular injection, indicating that the 3 cc dose was sufficient to immunize a calf (Koprowski and Black, 1954b) The Flury HEP virus has been tested in more than 1,000 human subjects where the vaccine was given by intramuscular or intradermal injection, and there have been no serious reactions (Fox et al, 1957, Sharpless et al, 1957) The effectiveness of the vaccination procedure used in the tests in man has been determined by testing the blood serum of vaccinated subjects for virus neutralizing substance Studies of immunization of dogs with Flury LEP live virus vaccine and Semple type killed-virus vaccine have shown that it is not uncommon to have immunity to street virus, as determined by challenge inoculation, in dogs whose serum contains no readily demonstrable virus neutralizing substance (Koprowski and Black, 1952; Johnson, 1954). The serologic method of rating a vaccine may result in accrediting a nonprotective vaccine because of the demonstration of nonspecific virus neutralization in the test as done and eliminating a protective vaccine because of the failure to demonstrate regular production of virus neutralizing substance in the blood of the vaccinated subjects. The results obtained in serum-virus neutralization tests with brain-fixed test virus may be different from those obtained with street virus (Johnson, 1948). The important thing is whether a vaccine produces immunity to infection with the natural virus The observation by Kissling (1958) that both brain-fixed and street virus will multiply in non-nervous tissue warrants consideration of the possibility that Flury HEP virus may multiply in man A certain minimum dosage is needed when a vaccine virus is inoculated into the muscle tissue in order to distribute the virus to susceptible tissues away from the point of inoculation as well as to seed the virus locally Vaccination by the intramuscular route with Flury LEP virus has been shown to be very effective in animals; until intradermal injection of the Flury HEP virus has been shown to produce immunity to the natural virus in dogs, monkeys or other large animals, it is not recommended for prophylactic immunization or postexposure vaccine administration in man All variations in methods of production of experimental live-virus or killed-virus vaccines for study in man and lower animals should be checked by submitting each lot of vaccine to protection tests in animals using street virus of salivary gland origin for the challenge virus Variation in dosage of the inoculum, route of inoculation, age of the chick embryo host and portion of the chick embryo used may be expected to yield differences in the ratio of various types of virus particles in the live virus vaccine. The important thing is to have a sufficient amount of the virus type in the vaccine which produces immunity to the neurotropic variant of the natural virus On the basis of animal experimentation it is reasonable to expect a high degree of immunity in man from a single intramuscular dose of 3 cc of Flury HEP vaccine virus of standard titer When used for

in the buttocks Skin testing must be done with the rehydrated serum diluted to 1 1,000 in physiologic salt solution, before giving the entire dose Persons showing skin sensitivity to horse serum may be treated by the desensitization procedure, giving injections of much-diluted serum and increasing the dosage at 20-minute intervals until the entire dosage is given Acute reactions, such as syncope, generalized urticaria, or angioneurotic edema, following the injection of horse serum, ordinarily may be relieved by injection of adrenalin and use of antihistaminics Acute reactions such as this and also the delayed serum sickness are uncommon in children, but the delayed serum sickness reaction is common in adults.

For persons known to have been bitten or scratched, vaccine or serum plus vaccine should be started immediately. (1) when the animal is apprehended and presents clinical signs of rabies, (2) when the animal is killed and the brain is found to be positive for rabies by microscopic examination, (3) when the animal is killed, and, though the brain is negative by microscopic examination, the animal is suspected of being rabid, and (4) when a person is injured by a stray animal that escapes or by one that cannot be identified Vaccine is rarely indicated when there is no satisfactory evidence of a person having been bitten The immediate administration of hyperimmune serum followed by vaccine beginning 24 hours later is recommended for all persons receiving severe bite exposure from rabid animals.

There are 2 types of killed-virus vaccine which are recommended (1) The Semple type packaged in 7 or 14 doses of 2 cc of 5 per cent or 0 5 cc of 20 per cent rabbit brain tissue infected with the Pasteur rabbit brain-fixed virus in physiologic salt solution containing 0 25 per cent phenol The virus is inactivated by incubation at 37° C The recommended procedure consists of 14 daily injections of vaccine given into the subcutaneous tissue of the abdominal wall, a different site should be used for each injection (2) The ultraviolet-light-irradiated or U V vaccine is similar to the Semple vaccine It is packaged in 7 doses of 2 cc of 5 per cent or 1 cc of 10 per cent rabbit brain tissue infected with the Pasteur rabbit brain-fixed virus in physiologic salt solution In this vaccine the virus is inactivated by ultraviolet irradiation. Merthiolate (thiomersal) at a 1:8,000 dilution or phenol at 0 25 per cent is added to the tissue suspension as a preservative. There is little difference in the antigenic qualities of the 2 killed-virus vaccines, and both have to pass the same antigen potency test

Vaccine should not be given unless there is good evidence of exposure to rabies. Sensitization to rabbit-brain tissue may produce serious allergic reactions Acute reactions, such as syncope, generalized urticaria, or angioneurotic edema, may occur soon after an injection of vaccine in persons who have been sensitized by previous vaccination. Persons who have not been sensitized previously are not apt to show any reaction until 7 or 8 days after the first dose The most common reaction is the development of erythema and edema about the site of vaccination with accompanying pruritis and pain These reactions tend to subside in a few days despite the continuation of treatment If local reactions are accompanied by fever, headache, nausea, lymphodenopathy and malaise, it is wise to stop the treatment This type of reaction is uncommon but usually precedes the development of more serious complications, such as encephalitis and paralysis. The paralytic phenomena, which may follow the administration of vaccine, include peripheral neuritis, dorsolumbar myelitis, and paralysis of Landry's type. Reactions characterized by paralysis seldom develop until 5 days after the first dose but may occur as late as 2 weeks after the completion of treatment. The peripheral neuritis most often involves the facial nerves, but other cranial nerves may be affected, recovery usually occurs in 2 or 3 weeks. Individuals who develop the dorsolumbar myelitis ordinarily recover This reaction is characterized by fever and gradual onset of weakness, numbness and tingling of the lower extremities, there may be urinary retention In cases of paralysis of the Landry's type, the onset is abrupt with high fever, headache, nausea, vomiting, girdle pain, urinary retention and ascending paralysis The paralysis may extend to involve the bulbar nuclei and terminate fatally More often the patient recovers rapidly, though in rare instances there may be permanent disability. Acute encephali-

demic of dog rabies in southern Rhodesia in 1902. Subsequently, this region was free of dog rabies until 1950 when the disease appeared among dogs along the border adjoining Bechuanaland This epidemic was controlled by the immunization of domestic dogs with the Flury LEP live-virus vaccine, but the disease is known to be present in wild life, and the existence of rabies in civet-cats, *Civettictis civetta*, has been confirmed by laboratory studies A few polecats, *Ictonyx striatus*, were diagnosed as rabid on the basis of observations (Adamson, 1954)

Rabies is especially common in India, for example, Veeraraghavan (1956) reported 1,475 human cases of hydrophobia in Madras State during the year 1941, and an incidence of more than 1,000 cases each year in this State through 1944. In 1954 there were 102 cases of human rabies in Madras State. The jackal, the fox and the wild dog are the common wild canine vectors of rabies in India The mongooses of the subfamily, *Herpestinae*, and the civets of the subfamily, *Viverrinae*, probably form the more important wild-life reservoir of the disease in India and elsewhere in Asia In Japan, rabies occurred in epidemic proportions in dogs in 1924, and there were 235 human deaths from rabies that year Vaccination of dogs with a Fermi type live-virus vaccine, using the rabbit brain-fixed virus, resulted in a sharp reduction in the incidence of dog rabies, and in 1932 only 63 cases of rabies were identified in dogs, and no human cases were reported (McKendrick, 1933) At the present time rabies does not appear to be established in domestic dogs in Japan Rabies has not been reported in Australia or the Hawaiian Islands It is of interest to note that the animal family of *Mustelidae* is not represented on these islands

In North America rabies was common in dogs in the New England States during the latter part of the 18th century The disease is known to have been epizootic in foxes in Massachusetts during the first decade of the 19th century (Thacher, 1812), in Alabama in 1890 (Wilkinson, 1894) and in Alaska in 1915 (Ferenbaugh, 1916) Since 1940, rabies has again become prevalent in foxes in eastern and southern United States (Johnson, 1945a) The focus of fox rabies which developed in New York State in 1945 (Korns and Zeissig, 1948) is still active, although dog rabies has been controlled effectively since 1947 In 1915 and 1916 rabies appeared in epidemic proportions in coyotes in California, Oregon and Nevada (Mallory, 1915; Geiger, 1916) It is the history of skunk rabies that suggests the true nature of rabies in wildlife in North America The earliest reference to skunk rabies in North America is that of Duhaut-Cilly who, when he visited Lower California in 1826, noted that the people there told him that skunks sometimes entered houses and bit people and gave them hydrophobia (Nelson, 1918) An epidemic of skunk rabies, which began in Kansas in 1873, was responsible for the death of at least 40 persons, mostly cowboys and hunters, who were bitten by rabid skunks when camping on the plains (Seton, 1925). Another epidemic of skunk rabies occurred in Arizona; it began in 1907 and continued through 1910, and at least 10 persons died after they were bitten by skunks (Yount, 1910) The small spotted skunk, *Spilogale putorius*, appears to have been the most frequent source of human infection, these animals are often referred to as phobey cats in western United States, because it is common knowledge that they have been the source of hydrophobia in human beings Although the recent epidemic of rabies in wildlife began in 1940, there was a sharp increase in incidence of the disease in wild animals in 1953, involving a great variety of animal species Skunk rabies appeared in epidemic proportions in Iowa, Minnesota, South Dakota, Texas and Wisconsin in 1953 and in California in 1954 Skunk rabies was reported in 24 states in 1955 (Chadwick, 1954, 1956) During epidemics of skunk rabies the principal vector in the striped skunk species, *Mephitis mephitis*, based on the recognized cases of rabies However, this may be more apparent than real, because this skunk is more closely associated with human habitation, as compared with the small spotted skunk, *Spilogale putorius*. There have been isolated cases of rabies in mink and weasels of the *Mustela* genus

The year 1953 marked the first time that rabies was identified in insectivorous bats in the United States During that year rabies virus was isolated from bats killed when attacking persons in daytime in Florida (Venters et al, 1954) and Pennsylvania (Witte, 1954) and from bats collected in Texas (Sullivan et al, 1954) Subsequently, rabies has been reported in insectivorous bats in 8 states (Enright, 1956) The species most commonly infected are the free-living, migratory, insectivorous bats of the *Dasypterus* and *Lasiurus* genera and the colonial, cave-dwelling Mex-

prophylactic immunization this should be sufficient for primary immunization, and a second or booster injection is recommended after exposure. For those not previously vaccinated there is a special problem in the use of a live virus vaccine, that is, the use of hyperimmune serum may interfere with the production of immunity from the vaccine because of inhibition of virus multiplication On the basis of results obtained in serum-virus neutralization tests of blood serum from vaccinated subjects there is some evidence that the prior use of hyperimmune serum interferes with the production of virus neutralizing substance by either killed-virus or live-virus vaccine (Atanasiu et al, 1956) However, Koprowski (1954b) found that the combination of hyperimmune serum and Flury LEP live-virus vaccine was more effective for post-exposure protection in dogs than either serum or vaccine alone The evidence at hand seems to be sufficient to warrant recommendation of the Flury HEP live-virus vaccine for use in man as a prophylactic vaccine for those subject to high risk of exposure to rabies. Its use for postexposure protection is indicated for those that have had previous administration of brain tissue vaccine and those that develop signs of sensitization to the brain tissue vaccine. Studies of various schedules of inoculation in dogs, monkeys or other large animals are indicated to determine the best dosage and spacing of injections for post-exposure protection with Flury HEP live-virus vaccine used alone and following hyperimmune serum.

EPIDEMIOLOGY

There are two epidemiologic types of rabies: the natural disease as it occurs in the wild animal host and the encephalitic type which is maintained in dogs. The current world-wide distribution of rabies is due to the general popularity of dogs as pets Domestic dogs revert easily to a semiwild or scavenger-existence, and stray dogs increase rapidly in any urban community unless an organized effort is made to destroy them

The early history of rabies in Europe indicates that the disease was endemic in certain regions which served as starting points for recurrent migrating epidemics of wolf and fox rabies The disease was limited by certain geographic barriers, such as mountain ranges and water, as well as by the abundance and the distribution of suitable hosts capable of spreading the infection Once established in domestic dogs, these limiting factors were much less effective, as dogs could travel with their masters from city to city and from country to country, furthermore, these animals were sufficiently numerous in any large city to maintain the disease once it was introduced. Dog rabies became very prevalent in Europe during the first half of the 19th century (Koch, 1930). In recent years the incidence of the disease has been low in western Europe; and the British Isles, The Netherlands, Denmark, Norway, Sweden and Switzerland have remained free of dog rabies

Rabies is known to exist throughout southwest Asia The disease has been known for a long time in Kenya and occurred in epidemic proportions among jackals from 1912 to 1916 (Hudson, 1944). A disease of dogs, known as oulou-fato, which exists in West Africa, has been identified as rabies, but it seems improbable that the disease is maintained in dogs or related wild animals of the family *Canidae*, in this region Human rabies is seen rarely in West Africa, and the disease is uncommon in dogs (Nicolau et al, 1933) Furthermore, the occurrence of paralytic rabies in dogs that are kept confined in compounds and not exposed to other dogs suggests that a small mammal is the vector in West Africa. In 1949, a variety of rabies virus of the oulou-fato type was isolated in the Belgian Congo (Delville and Jezierski, 1950). Rabies was recognized for the first time in South Africa in 1892 when it appeared in dogs in and around Port Elizabeth. Subsequently, there were occasional outbreaks of dog rabies which were brought under control quickly by rigid dog control regulations Between the outbreaks of dog rabies there have been repeated instances of human infection with rabies from the bite of the yellow mongoose, *Cynictus penicillata*, and this animal is considered to be the principal wild life vector in South Africa (Snyman, 1937) However, it may be that other members of the subfamily, *Herpestinae*, or the subfamily, *Viverrinae*, are the natural hosts of the disease. On the basis of general ecology, the cape polecat, *Ictonyx striatus*, the African weasel or snake mongoose, *Poecilogale albinucha*, and the civet-cat, *Civettictis civetta*, would seem to be the more likely hosts of rabies in South Africa There was an epi-

eral involvement of wildlife with rabies An abundance of susceptible hosts is a necessary feature of the development of epidemic rabies The increase in population of vampire bats in Mexico, Central and South America was brought about by the development of large cattle ranches, which furnished a ready source of blood for this hematophagous mammal The type of infection which developed in the vampire bat is a blind end in the ecology of the virus in that it is not perpetuated by the animal infected by bat-bite, i.e., they develop the paralytic form of the disease and do not become vicious and bite Therefore, the virus may have a cycle of infection which is like that of the true natural host where the perpetuation of the virus does not depend on the development of encephalitis in the infected animal, for instance, transmission by a cycle involving the infection in the breast tissue or the kidney One can assume that infection by bite in fighting among bats would not be so apt to produce the nonencephalitic type of infection noted in the vampire bat

The ecology of weasels of the *Mustela* genus is not so very different from that of the vampire bat The weasel exhibits a preference for feeding on blood They are good climbers and would likely prey on bats found in treeholes and on the branches of trees Vampire bats living in hollow trees would be likely prey for weasels, and colonial bats which live in caves would be taken by this animal as well There are many members of the families *Mustelidae* and *Viverridae* which have habits similar to that of the weasel in North America The small spotted skunk, *Spilogale putorius*, evidently plays an important part in the ecology of rabies virus in North America This skunk is a good climber and could thus serve to spread the infection to bats

The existence of rabies virus in the families *Mustelidae* and *Viverridae*, may be the equivalent of a built-in antibiotic against the carnivores of the family *Canidae* The virus does seem to be a major factor in controlling the population of wolves, foxes, jackals, coyotes and wild dogs There is the possibility that the virus is a natural disease of small mammals such as voles and bats, and that they perpetuate the virus during interepidemic periods, but this seems unlikely on the basis of present knowledge of the epidemiology of rabies

There has been a sharp reduction in the incidence of dog rabies in the United States during the past few years The enforcement of proper dog-control regulations and vaccination of domestic dogs with the very effective Flury LEP live-virus vaccine can be expected to eliminate dog rabies from any community within a few months The incidence of rabies in man has been reduced also; for example, in 1908 there were 111 human rabies cases in the United States (Stimson, 1910) compared with only 5 cases of rabies in man recorded in 1955 (Chadwick, 1956)

The attack rate of rabies in human beings bitten by rabid animals depends on several factors, for example, a rabid animal may not have the virus in its salivary glands, protection provided by clothing may be so great that little or no virus enters the wound produced, the natural source of the virus may be such that it is not very infectious for man, and virus may be removed from open wounds by cleansing with soap and water Nevertheless, the susceptibility of man to canine rabies appears to be relatively great Fetherston and Cooper (1932) observed 4 cases of rabies in 8 sailors bitten on their hands by a stray dog which they had picked up in a Chinese port and taken on board a destroyer, the bites of wolves are particularly dangerous as shown by the statistics given by Baltazard (1954), who recorded 60 rabies deaths, a mortality rate of 18 per cent, among 325 persons bitten by rabid wolves and given postexposure vaccine, and 53 rabies deaths, a mortality rate of 28 per cent, among 186 persons bitten on the head, despite vaccine administration Veeraraghavan (1954) arrived at a mortality rate by including only those bitten by an animal proved to have transmitted rabies to persons or animals In this category he recorded 19 rabies cases, a rate of 43 per cent, among 44 persons that did not receive the vaccine, and 10 rabies cases, a rate of 8 per cent, among 120 persons receiving a full course of vaccine The most extensive statistics as to attack rate of rabies in man are those of Schuder which, as quoted by Kraus et al (1926), list 1,325 rabies deaths in a group of 14,959 persons bitten by rabid animals, a rate of 9 per cent This information was obtained from records antedating vaccine prevention Of the first 214 patients with face bites treated at the Pasteur Institute in Paris, 12 or 5 6 per cent died of rabies despite vaccine administration The danger of bites about the head and the face is great, as shown by the statistics reported by Kraus et al (1926), a mortality rate of 11 per cent for children and 3 per

ican freetail or guano bat, *Tadarida mexicana*. The occurrence of epidemic rabies in Mexican freetail bats at Fort Sam Houston, Texas, and Carlsbad Caverns, Carlsbad National Park, N. Mex., in 1954, reported by Burns et al., (1956) is of particular interest because this bat is known to migrate to Mexico in the fall, returning the next spring (Villa, 1956). A *Tadarida mexicana*, banded at Carlsbad Caverns on September 18, 1952, was recovered in the caves of Las Garrochas, near Soyatlan del Oro, Jalisco, Mexico, on November 25, 1952, a flight distance of 800 miles. Another *Tadarida mexicana*, banded at a cave near Monterrey, Nuevo León, Mexico, January 29, 1956, was recovered at Carlsbad Caverns, N. Mex., on August 27, 1956, a flight distance of approximately 730 miles (Villa, 1956).

The history of rabies in the Far North goes back to 1870 when the disease was recognized in Greenland (Stimson, 1910). Subsequently, there were reports from time to time of a disease like rabies in wolves, foxes and sled dogs. Beginning in 1947, rabies was reported in foxes and wolves in widely scattered foci in the Northwest Territories. It was soon recognized that the disease was present throughout the entire Northern Territories of Canada, and the disease was identified as rabies by laboratory studies (Plummer, 1954). Rabies has also been identified in foxes and dogs in Alaska (Chadwick, 1956). Rabies is not recognized in the Arctic until it appears among foxes, wolves and sled dogs, but these animals do not seem to be able to perpetuate the disease in this region. Epidemics of rabies in the Far North coincide with periods of high population of lemmings of the *Lemmus* or *Dicrostonyx* genera and voles of the *Microtus* genus. The increase in population of the smaller mammals, in turn, results in an increase in the population of carnivorous animals which feed on them, and this may be the precipitating factor which produces epidemics of rabies. Of the *Mustelidae* in the Far North, it is the weasel or ermine, *Mustela erminea*, whose ecology suggests that it may be the natural host of rabies in the arctic regions.

Rabies has been identified in the mongoose species, *Herpestes auropunctatus*, in Puerto Rico (Chadwick, 1956), and it is of interest that this animal is not indigenous to this island but was introduced in the latter part of the 19th century as a means for controlling rodents.

The discovery that vampire bats are infected with rabies in some sections of Mexico, Central and South America is of considerable epidemiologic importance in that this animal is known to transmit rabies as a symptomless carrier. True vampire bats are found only in Mexico, Central and South America. The existence of rabies among vampire bats was recognized first in the State of Santa Catharina, Brazil. A paralytic disease of cattle and other livestock called *mal de caderas* appeared in epidemic form in that region in 1908. Some of the animals were proved to be infected with rabies virus (Carini, 1911). From the beginning of the outbreak, ranchers had observed that bats were flying in the daytime and fighting one another—unusual pheonomena—and that cattle bitten by bats during the day ordinarily developed paralysis and died within a few weeks. In 1916, rabies virus was isolated from a bat captured while feeding on cattle during the day (Haupt and Rehaag, 1921). On the basis of this finding, it was concluded that the repeated epidemics of paralytic rabies, which occurred in livestock in Brazil from 1908 to 1918, were due to infection induced by the bites of vampire bats. During the period 1931-1934, there was another outbreak of paralytic rabies in Brazil; rabies virus was isolated from naturally infected vampire bats, *Desmodus rotundus*, and this bat was shown to be able to transmit rabies for a period of 5 months as a symptomless carrier (Queiroz-Lima, 1934). A paralytic disease of cattle and man appeared in Trinidad, B.W.I., in 1925, but the disease was not identified as rabies until 1930 when the virus was isolated from a patient diagnosed as poliomyelitis (Hurst and Pawan, 1931, 1932). Subsequently, it was shown that the vampire bat, *Desmodus rotundus*, was the vector of rabies in Trinidad (Pawan, 1936a). The occurrence of an asymptomatic virus infection of the salivary glands in the vampire bat was confirmed by Pawan (1936b). Fifty-five cases of human paralytic rabies in Trinidad, presumably the result of bat-bite, were recorded by Verteuil and Urich (1936). In the course of a field study in the State of Michoacan, Mexico, during 1944, active agents later identified as rabies virus (Giron, 1944; Johnson, 1948) were isolated from a paralyzed cow and from the salivary glands of vampire bats captured in a cave located near the place where cattle were dying of paralysis.

Rabies in bats seems to be an aberrant cycle of the disease, part of the recent gen-

eral involvement of wildlife with rabies An abundance of susceptible hosts is a necessary feature of the development of epidemic rabies The increase in population of vampire bats in Mexico, Central and South America was brought about by the development of large cattle ranches, which furnished a ready source of blood for this hematophagous mammal The type of infection which developed in the vampire bat is a blind end in the ecology of the virus in that it is not perpetuated by the animal infected by bat-bite, i e, they develop the paralytic form of the disease and do not become vicious and bite Therefore, the virus may have a cycle of infection which is like that of the true natural host where the perpetuation of the virus does not depend on the development of encephalitis in the infected animal, for instance, transmission by a cycle involving the infection in the breast tissue or the kidney One can assume that infection by bite in fighting among bats would not be so apt to produce the nonencephalitic type of infection noted in the vampire bat

The ecology of weasels of the *Mustela* genus is not so very different from that of the vampire bat The weasel exhibits a preference for feeding on blood They are good climbers and would likely prey on bats found in treeholes and on the branches of trees Vampire bats living in hollow trees would be likely prey for weasels, and colonial bats which live in caves would be taken by this animal as well There are many members of the families *Mustelidae* and *Viverridae* which have habits similar to that of the weasel in North America The small spotted skunk, *Spilogale putorius*, evidently plays an important part in the ecology of rabies virus in North America This skunk is a good climber and could thus serve to spread the infection to bats

The existence of rabies virus in the families *Mustelidae* and *Viverridae*, may be the equivalent of a built-in antibiotic against the carnivores of the family *Canidae* The virus does seem to be a major factor in controlling the population of wolves, foxes, jackals, coyotes and wild dogs There is the possibility that the virus is a natural disease of small mammals such as voles and bats, and that they perpetuate the virus during interepidemic periods, but this seems unlikely on the basis of present knowledge of the epidemiology of rabies

There has been a sharp reduction in the incidence of dog rabies in the United States during the past few years The enforcement of proper dog-control regulations and vaccination of domestic dogs with the very effective Flury LEP live-virus vaccine can be expected to eliminate dog rabies from any community within a few months The incidence of rabies in man has been reduced also, for example, in 1908 there were 111 human rabies cases in the United States (Stimson, 1910) compared with only 5 cases of rabies in man recorded in 1955 (Chadwick, 1956)

The attack rate of rabies in human beings bitten by rabid animals depends on several factors, for example, a rabid animal may not have the virus in its salivary glands, protection provided by clothing may be so great that little or no virus enters the wound produced, the natural source of the virus may be such that it is not very infectious for man, and virus may be removed from open wounds by cleansing with soap and water Nevertheless, the susceptibility of man to canine rabies appears to be relatively great Fetherston and Cooper (1932) observed 4 cases of rabies in 8 sailors bitten on their hands by a stray dog which they had picked up in a Chinese port and taken on board a destroyer, the bites of wolves are particularly dangerous as shown by the statistics given by Baltazard (1954), who recorded 60 rabies deaths, a mortality rate of 18 per cent, among 325 persons bitten by rabid wolves and given postexposure vaccine, and 53 rabies deaths, a mortality rate of 28 per cent, among 186 persons bitten on the head, despite vaccine administration Veeraraghavan (1954) arrived at a mortality rate by including only those bitten by an animal proved to have transmitted rabies to persons or animals In this category he recorded 19 rabies cases, a rate of 43 per cent, among 44 persons that did not receive the vaccine, and 10 rabies cases, a rate of 8 per cent, among 120 persons receiving a full course of vaccine The most extensive statistics as to attack rate of rabies in man are those of Schuder which as quoted by Kraus et al (1926), list 1,325 rabies deaths in a group of 14,959 persons bitten by rabid animals, a rate of 9 per cent This information was obtained from records antedating vaccine prevention Of the first 214 patients with face bites treated at the Pasteur Institute in Paris, 12 or 5 6 per cent died of rabies despite vaccine administration The danger of bites about the head and the face is great, as shown by the statistics reported by Kraus et al (1926), a mortality rate of 11 per cent for children and 3 per

cent for adults bitten on the head by animals suspected of being rabid, despite administration of vaccine A false sense of security is given by statistics on vaccination against rabies as given by rabies treatment centers, as they ordinarily include only those cases of rabies that develop 2 or more weeks after the completion of the treatment, the assumption being that those developing rabies before that time do not represent failures For example, McKendrick (1940) in his 9th review of the statistics on rabies vaccination gave a reduced fatality rate of 0 48 for 490,670 cases of rabies exposure given the Semple killed-virus vaccine It is statistics such as those given previously that emphasize the necessity of giving hyperimmune serum in addition to vaccine in all severe bite exposures to rabies

CONTROL

Measures necessary for the eradication of dog rabies have been known for more than 100 years, they are measures which prevent any dog from biting another for a period of the longest latency of the disease The development of an effective live-virus vaccine for rabies has simplified the control of dog rabies The essential regulations include registration and licensing of dogs, seizure and destruction of stray dogs, and restraint of all owned dogs during the control program, which should include mass immunization of dogs with the Flury LEP modified rabies live-virus vaccine In order to ensure an effective control program there must be a uniform method for rabies control in the state jurisdiction and co-ordination of state programs through regional interstate organizations The public health officer responsible for the state rabies control program should be a veterinary medical doctor, on the staff of the communicable disease division of the state department of public health This official then is in a position to promote and develop rabies control programs in the counties when rabies infection is identified in animals A system of weekly reporting of clinical cases of rabies in animals is an essential step in a state rabies control program, and laboratory facilities must be available so that the existence of the disease in animals can be confirmed by laboratory studies prior to enforcement of control regulations The county rabies control program should be developed in co-operation with local agencies. A local rabies committee should be formed with representation including the local health officer, a physician, a veterinary medical doctor, the mayor of the city, the chairman of the board of supervisors, and representatives of the livestock, agricultural, dog-owner and animal-protection organizations, approved by the state health officer. This type of committee can arrange for the implementation of the recommended rabies control procedures which must be done by the city council and the board of supervisors. Local government must provide dog-pound facilities, personnel and equipment for stray-dog control and arrange for vaccination of dogs. The dog license fee is the proper source of funds for stray-dog control The county rabies control program should be initiated promptly after the identification of rabies

The Flury LEP modified rabies live-virus vaccine is recommended for the immunization of dogs. There is no scientific basis for the continuation of the use of the killed-virus vaccine for immunization of dogs The Semple type killed-virus vaccine is a good antigen but it has the disadvantage of producing occasional cases of paralysis from sensitization to the mammalian brain tissue in the vaccine, and the immunity produced by the killed-virus vaccine is not so great or long lasting as that obtained with the live-virus vaccine. The production of rabies vaccine from virus cultivated in chick embryos has the advantage that the virus can be obtained free of bacterial contamination, and it can be preserved by lyophilization so that the keeping qualities are much better than that of the killed-virus product Many commercial biologic laboratories now produce the Flury LEP modified live-virus vaccine, and the seed virus is available for use in governmental or commercial laboratories in other countries The experimental studies and field trials done some years ago with the Flury LEP live-virus vaccine showed that it was antigenic and that dogs immunized with the vaccine virus showed no serious reactions attributable to the virus in the vaccine (Koprowski, 1949; Cox, 1949; Tierkel et al, 1949) Subsequently, large-scale field trials were con-

ducted in the United States, Israel, Rhodesia and Malaya, and the use of the vaccine under field conditions confirmed the early reports as to safety and effectiveness (Kaplan et al, 1954, Adamson, 1954, Wells, 1954, Starr et al, 1956) The demonstration that a single intramuscular injection of 3 cc of the Flury LEP live-virus vaccine would produce 100 per cent immunity to street virus in dogs for 3 years, under experimental conditions (Tierkel et al, 1953), furnished scientific evidence of the superiority of this vaccine to killed-virus vaccine Several million dogs have now been immunized with the Flury LEP live-virus vaccine. Reactions reported following vaccination have been accounted for by factors other than the presence of the Flury LEP virus in the vaccine, for example, the occurrence of epidemic diseases other than rabies, such as canine infectious hepatitis and distemper, in dogs at the time of the vaccination program The Flury LEP virus does not invade the salivary glands, so there is no danger of spread of the virus from the saliva of vaccinated dogs

If rabies [redacted] present in dogs or cattle when a vaccination program is initiated, one can expect the occurrence of rabies in vaccinated animals for at least 1 month after vaccination, as the result of exposure to rabies prior to vaccination The postexposure vaccine protection effect was demonstrated in dogs immunized with a single injection of Flury LEP live-virus vaccine in Malaya, in that rabies deaths were not observed in vaccinated dogs more than 1 month after vaccination, although cases of rabies continued to occur in unvaccinated dogs (Westgarth and Wells, 1957) An epidemic of cattle rabies was reported by Wilcox and Hubbard (1957) where 24 of a herd of 62 cattle died of rabies at one dairy, without a definite history of animal-bite exposure A stray dog had been seen at the dairy shortly before the onset of the epidemic The cattle were not vaccinated after the discovery of the disease Vaccination of this herd after the appearance of rabies would have resulted in many apparent failures, or the rabies cases observed following vaccination might have been attributed to infection from vaccination This type of rabies outbreak in cattle may explain the results observed in one herd of cattle vaccinated with Flury LEP live-virus vaccine, reported by Starr et al (1956), and the cases of rabies attributed to the use of this vaccine in Honduras, reported by Schroeder et al (1952), where the vaccine was tested in cattle during an outbreak of paralytic rabies, presumably of vampire bat origin The known high susceptibility of cattle to rabies and the development of the Flury HEP virus strain of low pathogenicity for mammals prompted the testing of this virus in cattle, and it was found to produce a satisfactory immunity to street virus (Koprowski and Black, 1954b, Starr et al, 1956) The Flury HEP live-virus vaccine has been used for the immunization of more than 2 million head of cattle in Mexico, and it has had extensive field trial in Brazil and the United States (Camargo, 1955, Carneiro, 1954, Starr et al, 1956). There have been no serious reactions to the vaccine, and a single intramuscular injection of the vaccine has been found to be effective in preventing rabies under field conditions The Flury LEP live-virus vaccine has been found to be satisfactory for the immunization of domestic cats (Cox, 1953). The dosage recommended is 1 5 cc given by intramuscular injection into the thigh muscle The use of the Flury HEP live-virus vaccine for immunization of dogs is not indicated until satisfactory evidence is obtained that the immunity produced is equal to that obtained with the Flury LEP virus

Dog vaccination programs should provide for the immunization of all owned dogs, 4 months or older, with a single intramuscular injection of 3 cc. of the Flury LEP live-virus vaccine, given in the thigh muscle The vaccinated dogs must not be allowed to run at large until 30 days have elapsed after vaccination The duration of immunity can be expected to be at least 3 years, and revaccination need not be required within this period of time in a dog rabies control program Dogs under 4 months of age are to be confined at all times in an area declared as infected with rabies When rabies is present in a community, any dog that has bitten a person must be confined in a veterinary hospital or dog pound for at least 7 days to allow for observation for signs of rabies and to ensure that the animal does not escape This is very important because of the great

number of dog bites observed in urban communities If the biting dog disappears, one must begin rabies vaccine administration immediately, because there is no way to determine that the dog did not have rabies When a rabid dog is discovered, every effort should be made to locate all other animals that were exposed to it so that they may be destroyed or vaccinated and kept in quarantine for 90 days For dogs previously vaccinated with the Flury live-virus vaccine, revaccination is recommended, and the quarantine period may be reduced to 30 days

Epidemic rabies in wild animals, such as wolves, foxes, coyotes, jackals and skunks, may be combatted by hunting and trapping. The U S Fish and Wildlife Service has trained personnel to supervise this type of work The use of poison-bait is effective but must be done by trained personnel If the hosts of the epidemic disease in wild animals are reduced drastically in number in and around a focus of rabies, the disease may be controlled quickly in this area (Johnson, 1945a) If this is not done, the disease will kill most of the animals anyway, and in the meantime the infection will have spread to other regions. The endemic foci of rabies have not been defined for lack of knowledge of the nature of the infection in the reservoir host When this is determined, methods can be developed to prevent the spread of the disease from such foci. It is inexcusable for any community to permit the existence of dog rabies and so endanger the public to this terrible disease

entists and the public through the medium of the National Foundation for Infantile Paralysis Never before has such extensive human experimentation been accepted by an informed public as occurred in the effort to control poliomyelitis.

Poliomyelitis is an acute febrile infection which causes as its most important result an inflammatory reaction in the central nervous system, producing in a variable proportion of cases a flaccid paralysis of irregular distribution, extent and permanence. The disease is caused by a small virus which very commonly infects the human alimentary tract rather generally all over the world. Usually, this infection causes no signs or symptoms of disease, though it may give rise to a minor illness which may be called "summer cold" or "intestinal flu" but cannot be accurately differentiated from any other trivial illnesses or even be recognized as an entity. In such instances, the virus grows harmlessly in the alimentary tract with occasional sorties into the blood stream or certain lymphatic channels The infection would be quite unimportant except that rarely, in relation to the total number of infected individuals, it invades the central nervous system by a route as yet imperfectly known and causes paralytic disease as the result of destruction of motor neurons in the medulla and the spinal cord

HISTORY

Poliomyelitis probably has been prevalent for a great many years, and in descriptions or old pictures of its disastrous results there are hints of its occurrence in periods that antedate the Christian era Only in the last 75 years, however, has it appeared in epidemic form

The name, acute anterior poliomyelitis, describes the very specific anatomic localization of the most characteristic pathologic changes due to this disease, the unique tendency of the virus to attack the anterior part of the gray matter of the spinal cord The disease is commonly known in English-speaking countries as infantile paralysis, a name well established by its original habits and general usage but misleading in that it implies a present predilection of the disease for infants Though it was primarily an infantile disease many years ago, it is not so in modern times and in countries where the disease is now most prevalent. It may still be considered an infantile disease at present in countries with poor sanitation, but it is also a rare and nonepidemic disease in these areas. The change in age incidence in civilized countries is of very great theoretic importance and will be discussed later.

Although this disease has been known since antiquity, one of the first accurate descriptions of some scattered sporadic cases was by Heine in 1840. For the next 50 years infantile paralysis continued to be a sort of medical curiosity which was frequently recorded in the literature. The disease also bears the name of Medin, 1890, since he apparently was the first to note an epidemic of any magnitude (44 cases in Stockholm during the summer of 1887). A little later Caverly, 1894, recorded a similar epidemic of 132 cases in Vermont, U.S.A But one of the early masterpieces of epidemiology was a monograph by Ivar Wickman, 1913, in which he analyzed the unprecedentedly large epidemic of 1905 in Sweden (1,031 cases). Although ignorant of the causal agent, Wickman was the first to present evidence for the transmission of the disease from person to person. Meanwhile, before Wickman's work appeared in English, Landsteiner and Popper, 1909, were able to show that a bacteria-free emulsion of spinal cord from a fatal human paralytic case reproduced the paralysis in monkeys within 7 to 14 days after it was injected into their brains This agent was soon shown to be a virus, and the foundation for modern research was laid.

Poliomyelitis

(SYNONYMS. Acute anterior poliomyelitis, infantile paralysis, Heine-Medin disease, *Kinderlahmung, poliomyélite*)

INTRODUCTION

When the previous edition of this book appeared in 1952 the control of paralytic poliomyelitis was still in the blueprint stage. Now, a great reduction of incidence and possibly even eradication of the disease is feasible in many countries of the world

The unfolding story of this successful enterprise is one of the most dramatic in modern medicine. The success is especially a tribute to the importance of basic research in contributing new methods for approaching a chronically baffling problem The most important part of the story is the appearance of a new type of co-operative effort between sci-

EDITOR'S NOTE ENTEROVIRUSES. The 3 poliomyelitis chapters and the 2 chapters that follow are devoted to common virus diseases of late summer that are due to small viruses readily isolated from fecal specimens The chapters are arranged in order of seniority and the relative importance of the diseases The polioviruses are distinguished by their morbid effects in man and monkeys, the Coxsackie viruses by the lesions they induce in mice and the striking resistance to infection that mice quickly acquire after birth The ECHO viruses have no established pathogenicity for experimental animals They are cytopathogenic enteric viruses, without the characteristics of polio or Coxsackie viruses, that may be cultivated on human or monkey cells in vitro and are unrelated to other established viruses that, at times, may be recovered from the intestinal tract

A provisional classification and identification of the ECHO viruses was undertaken in 1955 by a committee of the National Foundation for Infantile Paralysis, and now 20 ECHO viruses have been recognized and identified by Arabic numerals The Foundation has also prepared typing sera to assist investigators in the identification of polio, Coxsackie and ECHO viruses The committee has suggested that the 3 groups be considered as members of a family of ENTEROVIRUSES (Committee on ECHO Viruses, Science, 1955, *122*, 1187-1188) This is consistent with the proposal of a Family of ENTEROVIRACEAE of the Order VIRALES which would include a Tribe of PARVOVIRAE (Dalldorf, G, Annals N Y Acad Sc 1953, *56*, 583-586) The 3 groups could properly be considered Genera within that Tribe

These suggestions will doubtless be reviewed by

among strains of the same antigenic type have made the characterization of certain types difficult Strain differences are reflected in striking variations in pathogenicity for both animals and cultured cells For example, the original strains of ECHO 9, isolated from healthy children, were devoid of pathogenicity for mice, while the epidemic strains of 1955 and 1956 were pathogenic for these animals and were recognized as Group A Coxsackie viruses This virus has now been properly designated a Group A virus (type 23) (Sickles, [redacted] M., in preparation) Other ECHO viruses may be reassigned after their properties are fully recognized

The growing realization that a number of Coxsackie and ECHO viruses are capable of inducing paralysis in man and poliomyelitislike lesions in monkeys provides additional justification for considering the 3 groups to be related and deserving of the attention that the several ENTEROVIRUSES are now receiving

entists and the public through the medium of the National Foundation for Infantile Paralysis. Never before has such extensive human experimentation been accepted by an informed public as occurred in the effort to control poliomyelitis.

Poliomyelitis is an acute febrile infection which causes as its most important result an inflammatory reaction in the central nervous system, producing in a variable proportion of cases a flaccid paralysis of irregular distribution, extent and permanence. The disease is caused by a small virus which very commonly infects the human alimentary tract rather generally all over the world. Usually, this infection causes no signs or symptoms of disease, though it may give rise to a minor illness which may be called "summer cold" or "intestinal flu" but cannot be accurately differentiated from any other trivial illnesses or even be recognized as an entity. In such instances, the virus grows harmlessly in the alimentary tract with occasional sorties into the blood stream or certain lymphatic channels. The infection would be quite unimportant except that rarely, in relation to the total number of infected individuals, it invades the central nervous system by a route as yet imperfectly known and causes paralytic disease as the result of destruction of motor neurons in the medulla and the spinal cord.

HISTORY

Poliomyelitis probably has been prevalent for a great many years, and in descriptions or old pictures of its disastrous results there are hints of its occurrence in periods that antedate the Christian era. Only in the last 75 years, however, has it appeared in epidemic form.

The name, acute anterior poliomyelitis, describes the very specific anatomic localization of the most characteristic pathologic changes due to this disease, the unique tendency of the virus to attack the anterior part of the gray matter of the spinal cord. The disease is commonly known in English-speaking countries as infantile paralysis, a name well established by its original habits and general usage but misleading in that it im-

is now most prevalent. It may still be considered an infantile disease at present in countries with poor sanitation, but it is also a rare and nonepidemic disease in these areas. The change in age incidence in civilized countries is of very great theoretic importance and will be discussed later.

Although this disease has been known since antiquity, one of the first accurate descriptions of some scattered sporadic cases was by Heine in 1840. For the next 50 years infantile paralysis continued to be a sort of medical curiosity which was frequently recorded in the literature. The disease also bears the name of Medin, 1890, since he apparently was the first to note an epidemic of any magnitude (44 cases in Stockholm during the summer of 1887). A little later Caverly, 1894, recorded a similar epidemic of 132 cases in Vermont, U.S.A. But one of the early masterpieces of epidemiology was a monograph by Ivar Wickman, 1913, in which he analyzed the unprecedentedly large epidemic of 1905 in Sweden (1,031 cases). Although ignorant of the causal agent, Wickman was the first to present evidence for the transmission of the disease from person to person. Meanwhile, before Wickman's work appeared in English, Landsteiner and Popper, 1909, were able to show that a bacteria-free emulsion of spinal cord from a fatal human paralytic case reproduced the paralysis in monkeys within 7 to 14 days after it was injected into their brains. This agent was soon shown to be a virus, and the foundation for modern research was laid.

CLINICAL PICTURE

Terminology

It is necessary to define several terms which are used commonly in discussing poliomyelitis.

Infection and Nonapparent Disease. Most poliomyelitic infections produce no signs or symptoms whatever and can be established only in the laboratory (Schabel et al., 1950, Bodian and Paffenbarger, 1954, Bhatt et al., 1955, Howe, 1958). This applies in almost equal degree to the identification of "abortive" poliomyelitic infection or "summer grippe" which almost certainly spares the central nervous system. But the name may be changed to the "prodrome," the "first illness," or the "minor illness" if paralysis later ensues (Horstmann, 1949). In

this uncertain state, the accuracy of guesses is considerably increased but by no means made certain if a mild febrile illness is detected in an epidemic setting characterized by frank paralysis or other signs of central nervous system invasion in other members of the family or close associates. Unfortunately, the most accurate method of diagnosis is retrospective, namely, a 4-fold or greater rise in the titer of specific serum antibody against some type of poliovirus Two bleedings must be obtained spanning an interval of 2 to 4 weeks While the isolation and the typing of poliovirus from the patient usually indicates the etiology, it is not positive proof, since occasionally a single individual may harbor more than one virus which is capable of evoking disease (Rhodes et al. 1950, Melnick et al, 1951, see section on Diagnosis)

The "*preparalytic stage*" of the disease is obviously the course up to the point of recognition of paralysis In those instances in which paralysis does not occur, this term is not applicable, we speak then of a nonparalytic course of the disease

"Bulbar poliomyel...
tinction
part of
volved, as judged by the clinical symptoms The term, though a poor one, is established in medical literature and refers to the type of disease that attacks predominantly the medulla or bulb of the brain and manifests itself by disturbances of the respiratory or vasomotor centers and by paralysis of the palate, the pharynx and the larynx The term is often used inaccurately for paralysis of muscles deriving their nerve supply from above the medulla, such as oculomotor and facial paralysis. The term is quite misused when it refers to respiratory paralysis due to involvement of the intercostal and diaphragmatic muscles We use it in this chapter in the usual though inexact sense, referring to brain-stem involvement It certainly would be clearer and more practical to refer only to the paralyzed muscle groups as pal-

...that it refers to a mild nondescript illness which may occur without any central nervous system symptoms and can be presumed to be due to the virus of poliomyelitis only because it occurs in members of a family coincidentally with an acute and definite case of poliomyelitis. It may well be associated with a viremia which does not lead to central nervous system involvement, but this has not been proved. Others use the term "abortive poliomyelitis" for the nonparalytic form of the central nervous system disease diagnosed by the clinical features and by the characteristic changes in the spinal fluid We use the term in the first sense.

The encephalitic type of the disease is a term used loosely when the patient's sensorium is particularly clouded

The Incubation Period

The incubation period of paralytic poliomyelitis is not definitely known Even during epidemic times, the presence of many asymptomatic alimentary infections, together with the protracted and frequently innocent appearing onset of paralytic disease in the primary case, has made it very difficult to determine accurately the time of effective exposure in those cases believed to be secondary

Casey (1942a, b) had a rare opportunity to study 36 cases (29 of them paralytic) which he had reason to believe were infected by a single exposure to a primary case They originated in a widely scattered rural population living in rough hilly country along "roads" which followed stream beds into blind ends without cross connections Opportunities for contact were rare and had fostered a local custom of elaborating a business transaction into a social event which involved two entire families spending the day together In this carefully scrutinized group, Casey found that the intervals from presumed exposure to the first symptoms ranged from 5 to 35 days and to paralysis 8 to 36 days, the latter averaging 17 days. In 14 highly susceptible chimpanzees fed virus and subsequently paralyzed, the time of exposure was more definitely known, and the incubation period to initial paralysis ranged from 7 to 31 days, with an average of 16 days (personal observations, H. H).

Outline of Clinical Course

The clinical course is as definite and points as dependably to a diagnosis as does the clinical picture of most other disease entities This statement should not imply that there are not frequent variations The clinical pic-

ture is studied best in the light of the usual sequence of events, which divides itself quite naturally into definite periods, and the differential diagnosis is discussed best with different emphasis for each period at which the disease may first be encountered Figure 62 in Chapter 23 shows the course graphically. It also shows the relationship of the finding of the virus and the occurrence of antibodies to the clinical features of the disease

It is always worthwhile to plot carefully in one's mind the time of onset and sequence of symptoms. Acute poliomyelitis is a disease of short duration, and its course does not vary much The ordinary febrile course consists of a rise of temperature associated with meningeal signs with or without paralysis, lasting a total of 5 to 7 days

Prodromal Stage A certain proportion of the patients show a preliminary rise of temperature for 2 or 3 days associated with no specific symptoms; this may be called a prodromal febrile stage and is followed by a period of well-being before onset of the ordinary febrile course It is quite possible for poliomyelitis to occur without any recognized febrile course, though any such instance should be studied with reasonable skepticism

The first hump of the temperature just referred to as a prodromal febrile stage (cf Fig 62, Chap 23) is made much of, but is seldom of aid in diagnosis. It is probably emphasized too greatly for the good of students, as it occurs in as little as 25 per cent of patients, the frequency probably depending on the acuteness of the observation of the family or the physician When the initial rise of temperature does occur, the resulting 2-humped temperature curve is termed the "dromedary course," this expression having been used by someone who thought the 2 temperature peaks resembled the humps of a camel It is unfortunate that the true dromedary has only 1 hump However, the term still persists

This prodromal or "dromedary" stage has acquired increasing interest with the knowledge that a viremia occurs, and many think that perhaps this represents the viremic stage of the disease This has not been shown by any adequate number of cases where the viremia was actually proved, and one can understand easily the difficulties of the situation since it is difficult to recognize until later that the illness is poliomyelitis.

The symptoms are nondescript during this period, and exact diagnosis at this time is impossible The spinal fluid is normal Suspicion of the disease can be aroused only because other members of the family or close associates are ill with infantile paralysis There may be slight fever and malaise, sometimes a headache or various gastro-intestinal disturbances, which ordinarily are passed off as a slight cold or "flu" or something equally trivial This first stage of the disease lasts from 1 to 2 days On the 4th to the 7th day following the first febrile rise, a second and definite abrupt rise of temperature takes place The same nondescript and mild symptoms may occur without being followed by any subsequent disease and constitute the "abortive poliomyelitis" referred to above

Preparalytic Stage. SYMPTOMS Three symptoms almost invariably occur at this time, i e, fever, vomiting and headache However, these symptoms are common to a great many diseases and in themselves do not lead to any particular diagnosis The fever is not high, usually under 103° F In the bulbar type of disease the fever is apt to be higher and to last over a longer period The vomiting is not like that caused by increased intracranial pressure and usually is not particularly forceful or projectile. It is associated with nausea. The headache is of moderate severity and constantly occurs though small children may not complain.

A variety of pains may occur, predominantly located in the back or the neck The neck pain often may not be reported as a "stiff" neck or back, and occasionally one gets a very illuminating story of a curious stiff gait possibly attributed to back sprain Usually the patient is sick enough to stay in bed, but it is not uncommon for him to remain ambulant up to the time of consulting a physician Although either diarrhea or constipation may occur, neither is common Sometimes constipation is very marked and seems definitely to be associated with atonia of the intestine Abdominal pain occasionally appears in the midepigastric region but is not ordinarily severe.

Physical Findings

The general appearance of the patient is of some diagnostic importance but actually cannot play a great part in establishing a diagnosis The patient is flushed and looks as if he had a temperature of 104° or 105° F., when actually his temperature is 101° or 102°, he is not greatly prostrated, is apt to be alert, co-operative, or even somewhat stimulated and talkative. The patient's skin is pink and flushed. A *tache cerebrale* which occurs also in many other diseases usually is demonstrated easily.

A positive tourniquet test or the easy appearance of petechiae on squeezing some part of the skin frequently can be demonstrated The pulse is fast, out of proportion to the actual fever and more in proportion to the appearance of the child Perspiration is marked and becomes more so as the disease progresses

Much emphasis must be put upon the detection of signs of central nervous system involvement, since it is by the demonstration of a characteristic type of stiff neck or back that a lumbar puncture is justified A dependable diagnosis of poliomyelitis in a preparalytic stage cannot be made without the demonstration of an abnormal spinal fluid

The rigidity of the neck and the back usually is not as marked as in meningitis and nowhere nearly as severe as in tetanus However, this varies and occasionally can be so striking that even parents notice it in their children and may report a curious, "stiff" type of gait The spinal rigidity is most marked in the cervical and the dorsal regions. It is demonstrated best, particularly in children, by asking the patient to sit up He may say he cannot, which may mean merely that he does not want to, though usually children will try If he co-operates a certain maneuver is characteristically carried out. He will turn on his side, push himself up on his hands and then turn around, sitting squarely on the bed but leaving both hands behind as a prop This is obviously to enable him to keep his balance without anterior flexion of the spine. If asked to put the chin on his sternum or on the examiner's finger put against the sternal notch, usually he will try to do so with careful, jerky, forward movements of his head and will open his mouth widely in an attempt to put his chin on the sternum with minimum flexing of the neck If a patient is lifted by his shoulders even with his co-operation, the head falls back, as if the neck were paralyzed. In fact, paralysis of the neck often has been wrongly diagnosed from this characteristic action. The patient allows the head to fall back not because it is paralyzed but because in that way painful flexion by his own muscle efforts is avoided. If the patient has any extensive neck muscle paralysis, he will not be able to turn his head from side to side, which he does fairly readily without pain when no paralysis exists.

A fine tremor often precedes by a few hours the development of paralysis. However, this should not be depended upon too greatly, because some patients will show quite marked tremors without subsequent paralysis developing. When it is seen localized in one extremity it can properly give the physician concern.

Paralytic Stage. It has been stated that paralysis may not occur. The temperature may become normal without any further symptoms. Muscle pain of considerable severity may occur, even if no paralysis is seen However, it is associated so often with paralysis that it is discussed in this section

Muscle pain varies considerably in individual patients and in different epidemics It is most marked during the early stage of paralysis and can be so severe and so localized as to imitate osteomyelitis or arthritis On the other hand, frequently such pain is absent. The presence of pain usually is evident from specific complaint by the patient; in young children or babies the fact that pain is present should be obvious from general observation while they are being handled.

Permanent damage to the central nervous system manifests itself almost exclusively by flaccid paralysis. Any other sequelae are hard to prove. Convulsions or upper motor neuron paralysis does not occur The disease does not affect permanently the sensory nerve cells, although it is possible that the pain of the acute stage of the disease is due to involvement of the posterior part of the cord. There is no disturbance of the sense of touch or pain Paralysis, when it occurs, usually will

be first evident on the 2nd, the 3rd or the 4th day after the first meningeal symptom Occasionally, paralysis will appear very rapidly in a few hours after the first sign of fever and occasionally as late as the 6th day. The peak of the incidence of paralysis is on the 3rd day. A reasonably good prognosis against the appearance of paralysis or an extension of it can be made by the time the temperature reaches normal, which is usually by the 5th or the 6th day, although it may be stated again that paralysis apparently due to poliomyelitis may occur without any recognized febrile illness

Because of pain or lack of co-operation of young patients, the certain detection of paralysis can be very difficult, and some reports of its extension late in the disease probably are due to earlier inaccurate observation Even a considerable degree of paralysis can be missed completely, particularly that of the paravertebral group of muscles and that occurring in young and un-co-operative children It is easy to understand that when pain or tenderness is marked, an evaluation of the extent of paralysis becomes difficult Although tenderness and paralysis often are associated, it does not certainly follow that a particularly tender muscle group will become paralyzed A physician often has the happy experience of finding that a tender muscle group, which he thought was paralyzed, shows good activity when the pain ceases Thus attempts to make an exact evaluation of paralysis are often futile in the acute stage of the disease when certain differentiation between inability and unwillingness to use a muscle is impossible

Characteristics of the Paralysis The paralysis of poliomyelitis is one of selected muscle groups It is not characteristic to have one extremity alone wholly paralyzed The paralysis in any muscle group can be of any degree, as it is obvious that a variable number of nerve cells can be destroyed Therefore, it is characteristic of poliomyelitis to cause a spotty paralysis, although in extensive involvement all the major muscle groups of an extremity may be completely lost Infantile [illegible]

of the paralysis does not follow the distribution of a nerve trunk such as the femoral or the glossopharyngeal nerve. Since a nerve trunk may derive its fibers from a fairly wide source in the cord or medulla, it is wiser to think of paralysis in terms of the muscles involved rather than of the nerve trunks supplying them. Large muscle groups of the extremities are paralyzed first and more extensively than the small muscles of the hands and the feet.

Detection of Paralysis The attempts at thorough muscle examination during the acute stage, especially when muscle tenderness exists, may be harmful as well as unsuccessful [illegible]

tion is necessary for prognosis as well as for planning treatment. An exact quantitative evaluation of the function of all muscle groups must remain the task of specially trained technicians, as over 100 separate muscle groups need to be tested and their power roughly quantitated However, the ordinary medical attendant should be able to detect paralysis adequately enough to give a dependable prognosis Careful observation of all spontaneous motions of an infant requires time but is of great value. For children a game can be invented easily whereby the examiner holds the child's arm or leg in some neutral position and then induces the small patient to resist motion in any direction

The physician always should be on the alert for the late discovery of paralysis originally missed Paralysis of the muscles of the trunk, particularly the abdominal muscles and the paravertebral groups, is apt to be overlooked and to lead to deforming scoliosis. Repeated muscle examinations should be carried out as carefully as possible at intervals of 2 or 3 months and then once again after 6 months or a year

"Bulbar" Type of Paralysis. The reported incidence of the bulbar form of the disease varies greatly as a physician's use of the term varies, but its incidence actually differs in different epidemics One case of bulbar paralysis for 8 or 10 cases of the spinal type is a reasonable expectation.

Much emphasis must be put upon the bulbar paralyses because of the high mortality in this group Paralysis of the face, the soft palate or

the pharynx—all called "bulbar" palsies—are frequently associated and are easy to recognize. Paralysis of the larynx is much more rare and is often difficult to detect clearly. Aphonia is uncommon but does occur A facial paralysis usually is associated with a palatal paralysis, and the latter with pharyngeal paralysis Either the palatal or the pharyngeal paralysis can occur alone Paralysis of the extrinsic muscles of the eyes is seen occasionally and usually is associated with one of the bulbar palsies

The recognition of a facial paralysis, which is, of course, of the central type, is easy Detection of palatal paralysis is made easy by the presence of a nasal voice and by the regurgitation of fluid through the nose on swallowing Pharyngeal paralysis likewise should be easy to diagnose but, nevertheless, resulting symptoms are frequently misinterpreted through inexperience Inability to swallow due to pharyngeal paralysis should be suspected and looked for whenever there is facial or palatal paralysis The first symptoms may be noisy, gurgling breathing and respiration which is irregular and interrupted The patient himself may not realize at first what the difficulty is, and the paralysis unfortunately may be demonstrated first by a severe choking attack following an attempt to drink Frequently, a doctor or a nurse may demonstrate the paralysis ill-advisedly by offering the patient a drink of water before the patient himself is aware of his disability. The patient may attempt to swallow a large mouthful: then he becomes frightened and begins to choke Sometimes in a paroxysm of fear, aspiration and laryngeal spasm may bring about severe anoxia with coma followed by a definite turn for the worse Great care should be exercised to avoid such episodes

Bulbar forms of poliomyelitis are associated with a longer and higher temperature course and with a more rapid pulse than in the usual spinal types of disease When the disease is fatal, frequently death is preceded by a period when the pulse is extraordinarily rapid, increasing hour by hour Rarely, there is a slow "vagal" pulse in acute bulbar poliomyelitis The blood pressure is not frequently elevated, but it may be so. It may also be greatly depressed Although the blood pressure may be elevated in a serious manner in later stages of the disease, it is interesting and puzzling that there is no necessary relationship between the two periods of hypertension Both hypertension and hypotension may occur with involvement of the medulla in the acute bulbar forms of poliomyelitis Hypertension occurs late in the course of this disease without any history that clearly points to brain-stem involvement at any stage The cause of this late hypertension is not clear. Renal stones are frequent in highly immobilized patients, but the occurrence of stones is not consistent with the hypertension The enormous reduction of the peripheral vascular bed with extreme muscular atrophy is also offered as an explanation of hypertension, but this seems inconclusive

LANDRYLIKE TYPE OF PARALYSIS Landry (1859) described a disease with paralysis progressing in the course of a few days from the feet and the legs to the trunk and upward to a fatal result with failure of the respiratory muscles or with bulbar symptoms He described also a descending paralysis with the same evidence of slow progression. Certainly, a picture like this occurs in epidemics of poliomyelitis and closely resembles the ordinary disease with pathologic findings similar to those of poliomyelitis

Encephalitic Type of Poliomyelitis. Although there is evidence from the pathology of the disease that poliomyelitis may attack any part of the central nervous system, clinical evidence of involvement of the higher brain centers is in most incidences meager. Ordinarily, the victim of poliomyelitis, except when *in extremis*, is mentally alert and shows none of the picture of encephalitis Sometimes, however, the sensorium is dull, there is excessive drowsiness, the patient is hard to arouse and presents a picture resembling that of tuberculous meningitis Except for this involvement of the general sensorium, we see little clinical evidence of encephalitis Intellectual defects as sequelae of poliomyelitis rarely, if ever, occur Upper-motor-neuron involvement producing a spastic paralysis must be extraordinarily unusual, although mentioned in early reports, and one should view with skepticism any such condition attributed to poliomyelitis Convulsions in poliomyelitis also are so rare that such a symptom should be considered as weighty evidence against

the diagnosis Many cases of encephalitis possibly caused by ■ related virus have been called poliomyelitis during epidemic times Modern virus studies do not support such diagnoses

Failure of Respiration. The final mechanism of death in any disease becomes almost a matter of philosophy. However, in poliomyelitis it seems more than usually logical to say that death is brought about by an immediate interference by the disease with the mechanism of respiration The analysis of such situations may by very difficult, but at some risk of oversimplication we can consider that efficient respiration may be prevented by 3 means

1 Disturbance of the nerve centers in the medulla or "bulb" which control respiration

2 The collection of mucus or vomitus around the glottis in patients with paralysis of the pharynx causing, either by actual obstruction or by setting up irritative spasms of the glottis, constantly interrupted inspiration and consequently shallow, irregular and ineffective respiratory efforts.

3 Actual paralysis of the primary respiratory muscles, the intercostals and the diaphragm

The lesions existing in the first and the second situations, involvement of the respiratory centers or paralysis of the pharynx, are in the medulla, therefore, this type of the disease commonly and properly is called "bulbar"

In the third situation, that with actual paralysis of the intercostal muscles or of the diaphragm, the lesion exists in the dorsal and the cervical sections of the cord Therefore, this spinal type of the disease should not be classed as "bulbar," although respiratory failure occurs

The respiratory difficulty in any patient ill with poliomyelitis may be due to one or to any combination of these 3 factors Paralysis of the respiratory muscles very frequently occurs alone without "bulbar" complications Paralysis of the pharynx, the palate or the facial muscles, all innervated from the medulla, very frequently is associated with apparent involvement of the "vital centers," most evidently the respiratory center. The marvelously complicated and congested mass of nerve paths and centers of the medulla makes it remarkable that such association does not always occur.

It is often difficult to ascertain the cause of the respiratory difficulty in the individual patient with "bulbar" poliomyelitis without paralysis of the intercostal muscles or of the diaphragm In some cases the respiratory disturbance seems to be purely "central" in origin and may make itself manifest by shallow irregular respirations or by jerky spasmodic inspiratory efforts, sometimes almost amounting to a succesion of hiccoughs

Pharyngeal Paralysis Pharyngeal paralysis alone can interfere with respiration, due to the existence of unswallowed pharyngeal secretions or vomitus which prevents the free passage of air through the larynx In pharyngeal paralysis often it is very difficult to be sure that there is not also some disturbance in the medulla of the nerve centers themselves controlling respiration It seems reasonable to hope that there is no "central" disturbance of respiration when the patient appears to be making conscious efforts to breathe carefully to clear his throat and seems to be alert to his own difficulties For many hours a patient may need consciously to plan every breath in a fatiguing effort to avoid aspiration Due to cumulative fatigue and anoxia, alert consciousness soon may be lost and be followed by a stage of semicoma with occasional periods of consciousness and fright, so that the condition is hard to distinguish from one due to a primary encephalopathy A very rapid pulse is characteristic of the bulbar form of poliomyelitis before death and is evidently a manifestation of the disturbance of the vagus nerve as well as the result of simple excitement and fatigue.

Respiratory Muscle Paralysis The early evidence of paralysis of the intercostal muscles or of the diaphragm may be difficult to recognize and to interpret Wakefulness, anxiety, restlessness, an increase ■ respiratory rate, the use of the alae nasi, a slight respiratory grunt, disinclinations to talk or a curious, frequently interrupted, monosyllabic speech all may precede more marked evidences of paralysis Cyanosis indicates severe paralysis and does not precede death by many hours.

In a child who will not co-operate by "taking a deep breath," it may be helpful in the demonstration of a partial paralysis of the

the pharynx—all called "bulbar" palsies—are frequently associated and are easy to recognize. Paralysis of the larynx is much more rare and is often difficult to detect clearly Aphonia is uncommon but does occur A facial paralysis usually is associated with a palatal paralysis, and the latter with pharyngeal paralysis. Either the palatal or the pharyngeal paralysis can occur alone Paralysis of the extrinsic muscles of the eyes is seen occasionally and usually is associated with one of the bulbar palsies

The recognition of a facial paralysis, which is, of course, of the central type, is easy. Detection of palatal paralysis is made easy by the presence of a nasal voice and by the regurgitation of fluid through the nose on swallowing Pharyngeal paralysis likewise should be easy to diagnose but, nevertheless, resulting symptoms are frequently misinterpreted through inexperience Inability to swallow due to pharyngeal paralysis should be suspected and looked for whenever there is facial or palatal paralysis The first symptoms may be noisy, gurgling breathing and respiration which is irregular and interrupted The patient himself may not realize at first what the difficulty is, and the paralysis unfortunately may be demonstrated first by a severe choking attack following an attempt to drink Frequently, a doctor or a nurse may demonstrate the paralysis ill-advisedly by offering the patient a drink of water before the patient himself is aware of his disability The patient may attempt to swallow a large mouthful, then he becomes frightened and begins to choke Sometimes in a paroxysm of fear, aspiration and laryngeal spasm may bring about severe anoxia with coma followed by a definite turn for the worse Great care should be exercised to avoid such episodes

Bulbar forms of poliomyelitis are associated with a longer and higher temperature course and with a more rapid pulse than in the usual spinal types of disease When the disease is fatal, frequently death is preceded by a period when the pulse is extraordinarily rapid, increasing hour by hour. Rarely, there is a slow "vagal" pulse in acute bulbar poliomyelitis The blood pressure is not frequently elevated, but it may be so. It may also be greatly depressed Although the blood pressure may be elevated in a serious manner in later stages of the disease, it is interesting and puzzling that there is no necessary relationship between the two periods of hypertension Both hypertension and hypotension may occur with involvement of the medulla in the acute bulbar forms of poliomyelitis Hypertension occurs late in the course of this disease without any history that clearly points to brain-stem involvement at any stage The cause of this late hypertension is not clear Renal stones are frequent in highly immobilized patients, but the occurrence of stones is not consistent with the hypertension The enormous reduction of the peripheral vascular bed with extreme muscular atrophy is also offered as an explanation of hypertension, but this seems inconclusive

Landrylike Type of Paralysis Landry (1859) described a disease with paralysis progressing in the course of a few days from the feet and the legs to the trunk and upward to a fatal result with failure of the respiratory muscles or with bulbar symptoms He described also a descending paralysis with the same evidence of slow progression Certainly, a picture like this occurs in epidemics of poliomyelitis and closely resembles the ordinary disease with pathologic findings similar to those of poliomyelitis

Encephalitic Type of Poliomyelitis. Although there is evidence from the pathology of the disease that poliomyelitis may attack any part of the central nervous system, clinical evidence of involvement of the higher brain centers is in most incidences meager. Ordinarily, the victim of poliomyelitis, except when *in extremis*, is mentally alert and shows none of the picture of encephalitis Sometimes, however, the sensorium is dull, there is excessive drowsiness, the patient is hard to arouse and presents a picture resembling that of tuberculous meningitis Except for this involvement of the general sensorium, we see little clinical evidence of encephalitis Intellectual defects as sequelae of poliomyelitis rarely, if ever, occur. Upper-motor-neuron involvement producing a spastic paralysis must be extraordinarily unusual, although mentioned in early reports, and one should view with skepticism any such condition attributed to poliomyelitis. Convulsions in poliomyelitis also are so rare that such a symptom should be considered as weighty evidence against

New tubes for collecting the fluid and new glass slides for examination of smears should be used Not infrequently, old and dead bacteria remaining on glassware from previous use may be stained again and cause serious confusion

SUGAR CONTENT The sugar content of the spinal fluid usually is normal or increased somewhat above average

EMOTIONAL DISTURBANCES IN POLIOMYELITIS

It is very evident that poliomyelitis is often accompanied by emotional disturbances which sometimes can be very severe Attention to these aspects of the disease has increased along with the greater interest in emotional disturbances that is now apparent in all medical practice In children this emotional disturbance may be seen, after the acute disease is past, by overactivity and incorrigibility (Coppelman, 1944) Many people are convinced that these changes in emotional reaction are more marked than after other acute infections

It has been questioned whether emotional disturbances are due to actual involvement of the brain by the virus of poliomyelitis It seems unlikely that this is so, since the virus does not directly attack any of the so-called "higher centers" outside the motor areas of the cortex, although at postmortem some histologic changes can be seen in all areas of the brain There are lesions in the thalamus, the subthalamus and the brain stem which conceivably could produce emotional instability Electroencephalographic studies (Holmgren, 1952) have been carried out in this disease (Grossman, et al, 1958, unpublished), and abnormalities have been found, but the electroencephalographic abnormalities seem to be found as frequently in patients without any of the so-called "encephalitic symptoms" EEG abnormalities have also been found in other acute diseases, for instance, in measles when there is no clinical evidence of encephalitis Therefore, the significance of these EEG findings must wait for more studies of many infectious diseases during the acute and the convalescent stages before conclusions regarding specificity can be drawn

Recently, as mentioned in the section on treatment, there has been a development of "Respirator Centers" where the worse handicapped victims of the disease—those with paralysis of respiratory muscles—are being treated very effectively and freed of their cumbersome assistive devices so they can return home Great attention has been paid to the emotional disturbance of these patients It would seem highly unlikely that psychic changes are more than might be expected in a highly publicized disease to which the public has become very sensitized and particularly in victims of the disease who themselves look with reasonable forebodings on their own future It would be expected that with the general knowledge of the crippling due to poliomyelitis, and the consequent increase and general fear of it, that a victim, knowing or suspecting his diagnosis, would fear the worst and that when actual paralysis does occur this fear would become greatly aggravated One vivid evidence of this with resulting physiologic disturbance is seen in patients with early respiratory muscle involvement Before they actually have severe paralysis, the patients overventilate and produce a mild alkalosis in themselves. This again might be a direct effect of the virus on the respiratory centers, although in all probability is not, but is simply another manifestation of a fear reaction This probability is more likely since similar hyperpnea is detected in patients with other respiratory handicaps such as asthma, as well as in patients frightened from other conditions than the disease itself. The emotional reactions take various forms, as they do in other diseases, attention to them, as phenomenon apart from virus effects, demands understanding care.

PROGNOSIS

General figures as to the fatality rate of poliomyelitis vary greatly (International Poliomyelitis Congresses, 1949, 1952, 1955) In New York in 1916 the fatality rate was reported as 21 4 per cent in 4,215 cases; in 1930 it was 16 8 per cent in 660 cases; in 1931 it was only 8 per cent in over 2,000 cases; in 1940 the United States fatality rate was about 10 per cent A reduction in reported fatality does not necessarily represent any lessening of the virulence of the disease but is in great part only evidence of an increasingly more astute diagnosis of the non-

muscles of respiration to inhibit the action, first of the intercostals, and then of the diaphragm, by splinting the chest or the abdomen with the hands and thus forcing the alternate respiratory muscles to greater action.

Postfebrile Course. After the fever has subsided, the clinical features of the postfebrile course of this disease are dominated by the picture of paralysis already described. However, certain other symptoms are evident, and it is clear that the disease attacks to some extent other parts of the central nervous system than the anterior horn cells. Vasomotor disturbances are evident during the acute stage of the disease, even though they are hard to define; they vary in intensity and might be considered no more prominent than in some diseases which do not attack the central nervous system Even without definite paralysis the patient is weak and unsteady as after any febrile illness. Complaints of easy fatigue, tachycardia, constipation, easy flushing and perspiration are made often and should be treated by rest and protection from overwork over a long period of convalescence

Clinical Laboratory Findings

Except from a study of the spinal fluid, the clinical laboratory has very little to offer of aid in the diagnosis or understanding of the course of poliomyelitis Poliomyelitis causes no change in the number or characteristics of red blood cells. Leukopenia is frequently seen early both in the human disease and in the experimental disease in monkeys However, there is not enough consistency in this finding to be of any dependable aid in differential diagnosis.

The spinal fluid is of great importance in the diagnosis of this disease during the acute febrile stage, although there are no changes in the fluid pathognomonic of poliomyelitis. One can say with some emphasis that, without characteristic paralysis, the diagnosis of

Characteristics of Spinal Fluid Globulin Content. The globulin content is increased fairly consistently. Statistically, the globulin is low at the early part of the disease, then rises fairly quickly and may be abnormally elevated for a considerable time after the end of the febrile period It is quite possible that the globulin test will be negative at the onset of the illness In the presence of an increase in the cell count of the spinal fluid the globulin test offers no additional information of value.

Cell Count. An increase in cells (normal; 0 to 8 per cu mm) appears within a few hours of the onset of fever and meningeal signs and usually persists during the febrile period. However, the cells may disappear in as short a period as 2 days or occasionally may be found in small numbers for some days after the temperature is normal In the majority of cases the cell count is normal after the first week. The gross appearance of the spinal fluid in poliomyelitis is described as clear, ground glass or hazy in appearance but rarely cloudy The usual range of the cell count is between 24 and 250 cells, but these figures do not represent rigid limits Any number of cells have been reported from 0 up to 2,000. Although the presence of a cell count over 1,000 is possible, the clinician should be especially critical in his differential diagnosis from meningitis.

The differential white cell count in the spinal fluid varies, the proportion of polymorphonuclear cells being highest at the beginning of the disease and the lymphocytes predominating later. With an individual case, however, little help can be derived from any but gross variations For instance, the finding of over 90 per cent lymphocytes in several hundred cells in the first few days of illness should put one on guard against a diagnosis of poliomyelitis There are no red cells in the spinal fluid of poliomyelitis victims except when th[illegible] the trauma of the lumbar [illegible] cells fr[illegible] since in the counting chamber red cells often appear as lymphocytes A second count should always be made of the spinal fluid drawn into a "white" pipet after the stem has been filled with glacial acetic acid to hemolyze the erythrocytes and thus prevent confusion, this technic should never be omitted and by its use spinal fluids bloody from trauma are still useful, if the white count, as in poliomyelitis, is significantly raised

TABLE 14 (*Continued*)

Year	Cases Reported		Deaths Reported		Ratio of Death Rate to Case Rate (Per Cent)
	Number	Rate per 100,000 Population	Number	Rate per 100,000 Population	
1950	33,300	22.0	1,904	1.3	5.7
1951	28,386	18.5	1,551	1.0	5.5
1952	57,879	37.2	3,145	2.0	5.4

(United States Public Health Service)

paralytic forms if, in fact, these are due to poliomyelitis virus. Probably a few deaths due to poliomyelitis are misdiagnosed, but a great many patients with nonparalytic form of this disease, or with very mild paralysis, have *not* been diagnosed at all. Therefore, the reduction in fatality rate as reported may represent an increased recognition of the milder forms of the disease, and in general it is found that in years and in areas where a high incidence is reported and where physicians are on the alert, a low fatality rate is found. Table 14 records the total incidence and death rate for the whole United States over the past 40 years. It can be seen that there is a general reduction of fatality rate with a general increase of incidence.

Prognosis in the Preparalytic Stage

At this stage we are most concerned with the probability of the appearance of paralysis. This preparalytic stage may, in fact, be a part of a nonparalytic course. Before modern techniques of tissue culture were available, of patients diagnosed as poliomyelitic in the febrile stage without paralysis from 50 to 70 per cent showed at least some slight evidence of paralysis to a skillful and careful examiner. However, probably not more than one fifth of all patients had paralysis greatly handicapping them in after life, although another fifth had a moderate paralysis which was temporary or not grossly incapacitating. However, such figures may now be challenged as more accurate viral diagnosis is available. Many patients diagnosed as nonparalytic poliomyelitis in the recent past are now being shown to have had infection with some other virus so that the per cent with paralysis will appear higher.

There is no dependable clinical or laboratory feature which will enable the physician in the preparalytic stage to make a prognosis that is anything better than an interpretation of old statistics. Although there is a tendency to believe that the higher the cell count in the spinal fluid the more severe will be the disease, this is not true. Although some statistical studies have been made which would seem to indicate a tendency the other way, there is no dependable relationship between fatality or severity of paralysis and the cell count which helps to determine the prognosis in an individual case. A fine tremor of one extremity exhibited in attempts to move it or to hold it extended sometimes precedes by a short period the paralysis of that muscle

TABLE 14 NUMBER OF POLIOMYELITIS CASES AND DEATHS REPORTED, CASE AND DEATH RATE PER 100,000 POPULATION[a] AND RATIO OF DEATH RATE TO CASE RATE, UNITED STATES, 1915-1955

YEAR	CASES REPORTED		DEATHS REPORTED		RATIO OF DEATH RATE TO CASE RATE (Per Cent)
	Number	Rate per 100,000 Population	Number	Rate per 100,000 Population

usually to be destroyed after one observation Intracerebral inoculation was necessary, and the subsequent disease had to be observed with autopsy confirmation usually determining the existence of the virus To determine the presence of antibodies, a mixture containing virus was first mixed with the substance suspected to contain antibodies, such as convalescent serum from a human patient or another monkey, and then injected into a monkey's brain in different proportions and doses in a crude attempt at titration. It is evident how ploddingly slow these studies had to be carried out over all these years Nevertheless, much was learned

The long-standing belief that only primates are susceptible to poliomyelitis was first shaken by the adaptation of the Lansing strain (now classified as Type II) to cotton rats and mice (Armstrong, 1939) The far-reaching effect of this discovery, which at last provided a cheap laboratory animal, is discussed in the section on Epidemiology During subsequent years further rodent adaptation was achieved with virus strains belonging to Type III (Li and Habel, 1951, Krech, 1954a), and later with Type I (Koprowski et al, 1947, Li and Schaeffer, 1953, Krech, 1954b) Infection was also produced with a Type II strain in embryonated eggs (Roca-Garcia and Jervis, 1955)

However, the important new hosts for poliovirus are now in-vitro cultures of non-nervous mammalian cells which were first described by Enders et al (1949) who produced viral multiplication in simple Maitland type cultures of several embryonic human tissues It is now known that a wide range of primate organs produce cells susceptible to poliovirus when grown in cultures The preparations most widely used are made from trypsin dispersed monkey kidney cells, either as a suspension (Salk et al, 1954) or grown out as monolayer cultures (Younger, 1956) Cell lines derived from malignant human tumors have also been employed extensively (Scherer, 1955) Recently, virus growth has been reported in chick cultures (Dunham and Ewing, 1957) and in cultures of rabbit embryo kidney (Sheffield and Churcher, 1957), but these findings need confirmation

Suffice it to say that the tissue-culture method has produced a revolutionary speed-up in the accretion of information about the biologic properties of poliovirus For example, the plaque method of tissue culture is sensitive enough to enable the identification of a single infective unit of virus and the study of its progeny (Dulbecco and Vogt, 1955) Also, the use of monkey-kidney cultures on a large scale has made possible the production of a vaccine for human use (cf Chap 24)

But tissue cultures are no longer animals, and it has not yet been possible to evaluate the importance of the changes in metabolism which induce in-vitro susceptibility to poliovirus in tissues apparently refractory in the intact animal This alteration emphasizes the need for some primate as a point for experimental reference The chimpanzee is the animal of choice for this purpose, since it shares with man sufficient susceptibility to acquire accidental poliomyelitic infection (Howe and Bodian, 1944, Howe, 1955, unpublished). Furthermore, chimpanzees are susceptible to oral inoculation by a wide range of strains of poliomyelitis virus While the paralytic rate is relatively low, virtually all of the animals without serum antibody become alimentary carriers of virus homotypic to that which they have ingested (Howe and Bodian, 1941b, Melnick and Horstmann, 1947, Howe et al, 1950, Howe, 1954, 1957) Therefore, the chimpanzee simulates man very closely in its reaction to the virus and is a most favorable animal for experiments in which this quality is of paramount importance In fact, the only recognized difference between the two species is the tendency of the chimpanzee to develop virus titers in the oropharynx higher than those of the stools, while the reverse appears to be true for man (Sabin, 1958, personal communication, Howe, 1958)

ETIOLOGY

The etiologic agent of poliomyelitis is a small virus This was established by the work of Landsteiner and Popper in 1909 when they showed that the intracerebral injection into a rhesus monkey of a bacteria-free emulsion from the spinal cord of fatal human cases caused a flaccid type paralysis characteristic of human poliomyelitis after 7 to 14 days They were able to transmit this disease from one infected monkey to others by the same

group, but fine tremors in some nonparalytic patients are exhibited quite generally in all their muscles Muscle tenderness may either conceal or simulate a paralysis. The presence of tenderness does not necessarily indicate that paralysis will occur.

The danger of occurrence of paralysis cannot be considered past as long as fever continues Usually the paralysis occurs in the 2nd or the 3rd day of the febrile period, but it may be the initial symptom to occur or it may be first detected late The likelihood of paralysis certainly becomes less as the temperature drops, although cases to the contrary are occasionally reported

Prognosis During the Acute Paralytic Stage

The prognosis for life depends upon the appearance of bulbar symptoms or paralysis of the respiratory muscles Many cases with palatal and facial paralysis occur without there being more serious complications, but difficulty in swallowing carries a more serious risk It is impossible to get accurate figures to express this in terms of percentage, since diagnostic criteria vary Certainly a large percentage of all bulbar cases will recover. A particularly high fever or rapid pulse must be considered as being especially serious Respiratory muscle paralysis varies from a barely discoverable weakness to complete loss of intercostal muscles and diaphragm. From experience with the respirator it is evident that considerable recovery usually takes place, in most instances enough eventually to permit breathing independent of a respirator, though unfortunately not necessarily with a capacity for normal life.

A dependable prognosis concerning the outcome of the paralysis found at this stage or an increase in its extent is impossible The paralysis that can be estimated during the acute stage of the disease is the worst that will occur, and some degree of recovery almost invariably takes place Occasionally, the recovery rate seems to be remarkable indeed, and extraordinary cases are encountered where extensive paralysis seems to disappear completely. Unfortunately, this is not generally true, and as a whole the worse the detectable paralysis, the worse the final crippling will be

Disturbance of motor function of the bladder and the intestine soon disappears Adequate function of the pharynx and the palate returns in a few weeks or a month in a considerable proportion of cases, though it is probable that permanent loss of function of many muscle fibers in these organs is as common as in other parts of the body. In some cases serious and permanent dysfunction results, and emotional factors play a big part Partial paralysis of the palate is easier to detect and, therefore, is more evident than that of the pharynx. The early absence of demonstrable paralysis should not be accepted as final

PATHOLOGIC PICTURE

The pathogenesis and histopathology are described in Chapter 23

EXPERIMENTAL INFECTION; HOST RANGE

It is not evident that any animal, other than man, is a natural host for the virus of poliomyelitis or is subject to disease from it The nearest approach to an exception to this statement is the chimpanzee, which in captivity has been known to acquire the disease from contact with other chimpanzees who had been infected experimentally. Furthermore, occasionally chimpanzees imported from Africa already show some neutralizing antibodies to poliomyelitis Nevertheless, it is not evident that the paralytic disease naturally occurs in these animals

The first animal to be given the disease experimentally was a rhesus monkey. Landsteiner and Popper, in 1909, were able to cause a paralytic disease in this animal by direct intracerebral injection of a bacteria-free emulsion of the cord of a human victim of the disease This experiment was the beginning of our understanding of the etiology of poliomyelitis, and for 30 subsequent years about all of our knowledge of experimental infection was derived from such costly experiments. The rarity and the high cost of these animals prevented large-scale studies and kept experiments at a level permitting scarcely more than "impressions" Each animal performed as a single expensive test tube

pH (3 8 to 8 5) for weeks but rapidly loses activity in more acid or alkaline media (Pollard and Connolly, 1949) and is very sensitive to oxidizing agents. Infectiousness diminishes very slowly in the cold, and specimens may be kept at 4° C. for months or even years if they are stored in 50 per cent glycerine-saline or some protective protein The titer of stools may be maintained without apparent diminution at −70° C for 8 years or more, despite exposure to CO_2 gas, nor is it greatly affected by repeated freezing and thawing (Howe, unpublished data) The virus also resists inactivation by alcohol, phenol, formalin, chlorine antibiotics, but, of course, is finally overwhelmed except by the last Nevertheless, several inactivating agents do not alter the virus sufficiently to destroy its antigenicity (cf Chap 24)

In view of the high prevalence of poliomyelitic infection in the summer months and in the tropics, it is surprising to find the virus rapidly rendered noninfectious by ultraviolet light (Jungblut 1937 Dick et al 1951), while its sensitivity to drying has made lyophilization impossible However, it must be admitted that these statements are based on the behavior of virus in spinal cord emulsions Virus survives in human feces for hours at summer heat and has been demonstrated in privy samples as well as in flies having access to exposed human feces (Trask et al, 1943 Trask and Paul, 1943) However, it is destroyed by routine pasteurization (62° C for 30 minutes), whether suspended in milk, cream, or ice cream (Kaplan and Melnick, 1952) but it is resistant to chlorination in proportion to the amount of organic material also present Lansing virus partially freed of cord emulsion is said to lose activity completely when exposed to 0 05 ppm of free chlorine at pH 6 85 to 7 40 for 10 minutes (Lensen et al, 1949) However, this tells little about the effectiveness of chlorination when water (especially in swimming pools) is continually subject to fresh contamination of virus mixed with pharyngeal mucus or feces In any event, the lack of evidence for the spread of poliomyelitis by swimming pools or municipal water supplies indicates that something tips the balance against the agent

Host Relationships to Infection

It is important whom one picks as his ancestors, since it is clear that selective breeding can create natural resistance to bacterial and neurotropic virus infection (Webster, 1937) Even with the random breeding habits of humans it appears that the susceptibility to paralysis is in some way hereditary This was noted some years ago by Aycock (1937), who observed that 51 per cent of poliomyelitis cases gave a history of poliomyelitis in some member of the family, while only 5 per cent of normal persons did. Obviously, it is important to pick a good control, one which resembles the group to be tested in every respect, except the quality in question. This is not easy when one is tracing family trees, but Addair and Snyder (1942) felt that they had evidence for an autosomal recessive gene in determining susceptibility to paralysis Perhaps the most interesting genetic studies of recent years are those dealing with twins One published recently by Herndon and Jennings (1951) contained a summary derived from an unselected series of 3,890 reported cases of poliomyelitis In this the authors found 45 pairs of twins, 33 dizygous and 14 monozygous, or identical. The rate for paralysis in both of the monozygous twins was 36 per cent a figure contrasted with 6 per cent in the nonidentical twins (X^2 — 6 81)

Viruses are clearly very susceptible to changes in their host and because of this they may be led in various directions For example the tissue cultures may yield so-called harmless mutants, which are not always stable and may revert to their old vicious ways when returned to the original animal host (Sabin, 1957, Koprowski et al, 1956 Dick et al, 1957)

The character of the animal host is most important for the survival of the virus, since viruses appear to be less readily adaptable to natural animal hosts than to the easy life in a tube All sorts of influences may be brought to bear on the virus by change in the host. These range from things as small as an increase in resistance to paralysis in mice receiving an inadequate diet (Foster et al, 1943), or an increased survival time in mice receiving an excess of methionine (Gershoff

technic. Within a short time the agent was identified as a virus which even in early experiments was found widely disseminated through the bodies of fatal cases, i e, in the spinal cord, the brain stem, throat washing, contents of the large intestine and occasionally in lymph nodes Although for years there was a dispute among some whether these experiments actually demonstrated a virus as the etiologic agent, in retrospect we are certain that the fact was well established at that time

In recent years this virus has been identified only in certain parts of the brain which characteristically show lesions (cf Chap 23) and in the walls of various levels of the alimentary tract (Sabin and Ward, 1941). Also, it has been found to circulate briefly in the blood during the early stages of infection (Bodian and Paffenbarger, 1954, Horstmann et al, 1954) A detailed study of orally inoculated chimpanzees (Bodian, 1956, Sabin, 1956) indicates that in this species, as in man, areas of initial growth for the virus are largely restricted to the alimentary tract with *frequent early involvement of its afferent* lymph nodes, and that there is also an inconstant and transient viremia It has been estimated that in 100 to 1,000 human alimentary infections of this general type, only one may reach the central nervous system to produce paralysis (Howe, 1949, Casey et al, 1950)

Classification of Virus

It was earlier suspected that all poliomyelitis viruses might not be the same Painstaking studies of many strains finally culminated in the knowledge that there were in fact 3 antigenically specific types These were first known by rather romantic names applied to designate a situation or person related to the isolation of the virus For instance, one of us (H.H) used the name Brunhilde which was the term applied to a noisy exhibitionist chimpanzee, the first of her species to yield virus. The name Lansing was given to a better-known strain which came from a patient in Lansing, Mich. The name of Leon was applied to a third strain from the name of a patient in California. With elaborate studies (Bodian et al, 1949, The Committee on Typing of The National Foundation for Infantile Paralysis, 1951), all strains were shown to fall into these 3 general groups and are now called simply Types I, II and III.

Physicochemical Properties of the Virus

Although the size of the poliovirus particle was originally estimated at 8 to 12 mμ by ultrafiltration of infected CNS through graded collodion membranes (Elford et al, 1935), tissue culture has made available an almost unlimited supply of virus already largely freed from extraneous proteins Utilizing this source, Sabin et al. (1954) published photographs of filtered spherical particles 25 mμ in diameter, which were thought to be the virus Schwerdt and Schaffer (1955) obtained similar results with highly purified samples of the Lansing and MEF_1 strains, utilizing methanol precipitation and differential high-speed centrifugation for the elimination of extraneous material. Furthermore, the particle associated with infectivity was found to be a nucleoprotein, as characterized by its ultraviolet-absorption spectrum It contains from 20 to 30 per cent ribose nucleic acid, which is of great interest since the Nissl bodies of nerve cells are also rich in RNA The question, as yet unanswered in this work (Schwerdt and Fogh, 1957) is the observation that the infectious unit appears to contain numerous physical particles, while Dulbecco and Vogt (1955) have indicated that a single particle is capable of initiating infection Recently, virus size has been measured by a different method, employing ionizing radiations (Henyesh et al, 1958). This technic involves determining the density of radiation required merely to abolish the demonstrable activity of the virus sample and provides data for calculating the size of each particle. This study furnishes important independent corroboration of the others

Recently, Colter et al (1957) and Alexander et al (1958) separated the RNA component of the virus particle from its protein part and succeeded in infecting host tissue with the RNA alone.

Resistance of Virus

Poliomyelitis is one of the most stable of known viruses It tolerates a wide range of

acquired (Aycock and Ingalls, 1946). There is little doubt of the effect of pregnancy itself Although many of the studies dealing with this matter are deficient in controls, this is not true for all (Anderson et al , 1952). Two small but well-reasoned studies are offered here as a model In the paper by Paffenbarger et al (1954) one is struck by the fantastically high attack rates for individuals from 25 to 34 years of age ("The parental years") These could be attributed with equal ease to increased susceptibility or to greater exposure to small children, the chief reservoir of virus In a subsequent paper (Paffenbarger and Wilson, 1955) this material was subjected to further analysis The data show a rate in pregnant contact 7 times that in a nonpregnant female group also in contact with a recognized case The poliomyelitis rate for pregnant married females was more than double that for nonpregnant married females or married males of comparable age

It had long been noted (Levinson et al , 1945, Russell, 1947, 1949, 1952, and Horstmann, 1950) that some of the most severe paralysis occurred in young people who were engaging in strenuous exercise at the onset of their illness Apparently, this is during the onset of illness and not some time before it

It seemed quite clear from their studies that the casual observations noted before could be supported by more caref[illegible] and that [illegible] ing [illegible] sys[illegible] poliomyelitis did result in a higher degree of paralytic involvement

Operative interference of any sort is also not without its dangers, although in general the public has decided to accept them There is no question of the increased risk of bulbar poliomyelitis following tonsillectomy, since virus can be found in the throats of symptomless individuals during the poliomyelitis season (Howe and Bodian, 1947) The immediate effect of tonsillectomy was first reviewed by Aycock in 1942, and it has been difficult to improve on his observations which show a concentration of bulbar cases 30 days after operation Top (1952) first noted a continued, though less striking predisposition to bulbar poliomyelitis in those who had had a tonsillectomy at any time, but it seems appropriate to return to the article of Paffenbarger and Wilson (1955), which also deals with tonsillectomy They showed that 43 per cent of the bulbar or bulbospinal cases had had a previous tonsillectomy, while this was true in only 8 to 11 per cent of other poliomyelitic infections and in 15 per cent of the control population

One need no longer worry about carious teeth as a portal of entry for poliomyelitis, despite the number of studies purporting to prove this, since in 1947 Finn, et al did a well-controlled study in which they found no difference in the prevalence of caries between 70 poliomyelitis patients and 119 siblings, who were subjected to the same conditions of exposure

A furor was caused some years ago by the discovery that injections of antigenic material, particularly pertussis and diphtheria vaccine, were prone to localize initial paralysis near the site of injection The phenomenon could be reproduced experimentally when viremia was induced artificially (Bodian, 1955),

et al., 1952) There are also other things which operate to change resistance to virus invasion, such as age Why is it that newborn mice are refractory to poliomyelitic virus when later on they are not (Sabin, 1950)?

There is an increased hazard of death or severe disability from "respiratory" paralysis in adults as shown in Figure 57. This was prepared from the records of carefully verified cases in Sweden, between 1925 and 1944 (Olin, 1952). The increased severity with advancing age has been confirmed independently, even to the decreased single leg paralysis and increased incidence of quadriplegia (Weinstein, 1957) The latter also noted a reversal of the preponderantly high rate among young males to females 16 to 39 years of age Since the rates for this age group are higher in both sexes than a decade ago, this probably represents increased exposure of susceptible subjects to small children, rather than the effect of pregnancy Table 15 indicates the extent to which paralytic poliomyelitis has crept insidiously into the age group of 15 to more than 25 years since 1916 to 1920. While the age specific rates are still low, the large denomination gives rise to numerous cases which contribute heavily to the undertakers and the respirator centers

There is considerable evidence that various effects in hormone balance may influence and increase the susceptibility to the paralytic consequences of poliomyelitis. Two observations in man seem to be related to this These are the vulnerability of pregnant women to severe paralysis and the increased risk of severe paralysis brought about by exercise during the invasive period of the disease. Perhaps the one most widely recognized is the increased vulnerability of pregnant women, foreshadowed by a 50 per cent incidence of still-births and abortions if poliomyelitis is

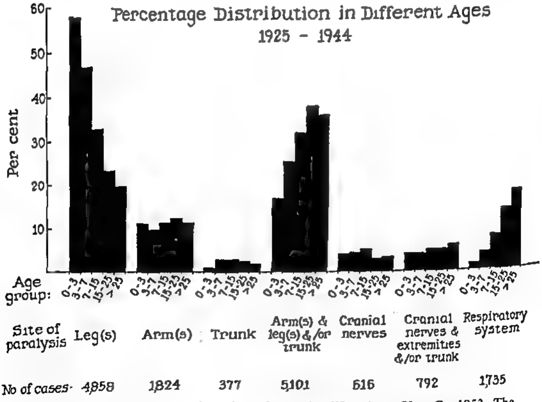

FIG. 57. Site and distribution of paralysis (Modified from Olin, G, 1952, The epidemiologic pattern of poliomyelitis in Sweden from 1905 to 1950 *in* Poliomyelitis Papers and Discussions Presented at the Second International Poliomyelitis Conference, pp 367-375, Philadelphia, Lippincott)

acquired (Aycock and Ingalls, 1946). There is little doubt of the effect of pregnancy itself. Although many of the studies dealing with this matter are deficient in controls, this is not true for all (Anderson et al., 1952). Two small but well-reasoned studies are offered here as a model. In the paper by Paffenbarger et al. (1954) one is struck by the fantastically high attack rates for individuals from 25 to 34 years of age ("The parental years"). These could be attributed with equal ease to increased susceptibility or to greater exposure to small children, the chief reservoir of virus. In a subsequent paper (Paffenbarger and Wilson, 1955) this material was subjected to further analysis. The data show a rate in pregnant contact 7 times that in a nonpregnant female group also in contact with a recognized case. The poliomyelitis rate for pregnant married females was more than double that for nonpregnant married females or married males of comparable age.

It had long been noted (Levinson et al., 1945, Russell, 1947, 1949, 1952, and Horstmann, 1950) that some of the most severe paralysis occurred in young people who were engaging in strenuous exercise at the onset of their illness. *Apparently, this is during the* onset of illness and not some time before it.

It seemed quite clear from their studies that the casual observations noted before could be supported by more careful study and that indeed intense physical activity during the invasion stage of the central nervous system infection by poliomyelitis did result in a higher degree of paralytic involvement.

Operative interference of any sort is also not without its dangers, although in general the public has decided to accept them. There is no question of the increased risk of bulbar poliomyelitis following tonsillectomy, since virus can be found in the throats of symptomless individuals during the poliomyelitis season (Howe and Bodian, 1947). The immediate effect of tonsillectomy was first reviewed by Aycock in 1942, and it has been difficult to improve on his observations which show a concentration of bulbar cases 30 days after operation. Top (1952) first noted a continued, though less striking predisposition to bulbar poliomyelitis in those who had had a tonsillectomy at any time, but it seems appropriate to return to the article of Paffenbarger and Wilson (1955), which also deals with tonsillectomy. They showed that 43 per cent of the bulbar or bulbospinal cases had had a previous tonsillectomy, while this was true in only 8 to 11 per cent of other poliomyelitic infections and in 15 per cent of the control population.

One need no longer worry about carious teeth as a portal of entry for poliomyelitis, despite the number of studies purporting to prove this, since in 1947 Finn, et al. did a well-controlled study in which they found no difference in the prevalence of caries between 70 poliomyelitis patients and 119 siblings, who were subjected to the same conditions of exposure.

A furor was caused some years ago by the discovery that injections of antigenic material, particularly pertussis and diphtheria vaccine, were prone to localize initial paralysis near the site of injection. The phenomenon could be reproduced experimentally when viremia was induced artificially (Bodian, 1955),

thus suggesting a similar mechanism for man in whom the demonstration of this effect rested chiefly on the reversal of the usual arm-leg ratio. This means that following injections, arm paralysis became more common than leg paralysis This was noted in material from England by Hill and Knowelden (1950), in Australia by McCloskey (1950) and by Korns, et al. (1952) in the United States Others found similar results, but, excepting a most extraordinary outbreak associated with injections for yaws (Rosen and Thooris, 1953) the risk of paralysis was not great enough to interfere with immunization programs The Field Trial of the poliomyelitis vaccine was monitored very carefully in the beginning to be certain that the vaccine itself would not act as a provoking injection (Melnick and Ledinko, 1952, Francis, et al., 1957)

DIAGNOSIS

The diagnosis of the paralytic type of poliomyelitis can be made by ordinary clinical technics with a great degree of accuracy by a physician with ordinary sophistication The classic picture of fever, headache, stiff back with clear sensorium, plus the appearance of the characteristic type of paralysis is almost pathognomonic of poliomyelitis As has been said wisely, the diagnosis depends upon a shrewd clinical suspicion plus the finding of an abnormal spinal fluid compatible with the disease However, the diagnosis of acute central nervous system poliomyelitis without paralysis cannot be made firmly by simple clinical observations even with spinal fluid data This could not be stated so emphatically a few years ago, but it is clear now that other diseases, such as those due to the Coxsackie viruses and some of the ECHO viruses, can produce a clinical picture and spinal fluid changes undistinguishable from nonparalytic poliomyelitis. One should not be led into a firm diagnosis of poliomyelitis simply because of the incidence of a present epidemic, since the seasonal occurrence of these different virus infections overlap

It is important to define the circumstances in which a specific diagnosis can be made by viral and antibody studies The finding of the virus by tissue culture technics from the stools or, more important, the pharynx of patients with acute disease is highly suggestive of the diagnosis but by no means confirms it We have emphasized earlier that there is a widespread distribution of virus in people without disease particularly in epidemic times. A disease due to another virus with coincidental infection from poliomyelitis virus is quite possible. However, if the acute serum and convalescent serum obtained some weeks after the acute illness is studied for antibodies, and an increase in antibodies to the specific type virus that was found in the stool or the pharynx occurs, it is possible to establish a firm diagnosis of acute poliomyelitis. However, it is evident that confirmation of diagnosis is thus made only after the disease has run its acute course. The demonstration of a sharp rise in antibodies to a specific type of virus immediately after an acute infection with compatible symptomatology, even without the demonstration of the virus itself, is also highly suggestive

To accomplish the demonstration of the virus and of increasing antibody levels to it one must use expensive technics which cannot yet be carried out regularly in all suspicious cases and, therefore, are not readily available to most physicians As was stated, the diagnosis thus established would not be useful for the immediate care of a patient, even if the laboratory facilities were available. Therefore, during the acute stage of a disease which may be preparalytic poliomyelitis there is no way to prove that the diagnosis is not poliomyelitis and to relieve worry and tension. With the presence of the characteristic paralysis all treatment presently available can justifiably be carried out without the final confirmation from the virus laboratory.

Differential Diagnosis

The differential diagnosis needs to be considered under conditions where no paralysis exists and also under conditions where paralysis or apparent paralysis appears. In the acute preparalytic or nonparalytic stage we have to differentiate between conditions which primarily involve the central nervous system and conditions associated with extraneural disease, where we have only symptoms of central nervous involvement such as in so-called meningismus Differential diagnosis in

the acute nonparalytic or preparalytic stage can be further subdivided into the problem that faces the clinician before, and again after, the spinal fluid is available for study.

The first problem is the differentiation before a lumbar puncture is done, which often means determination of the need for doing a lumbar puncture. It is clear that symptoms like those of acute preparalytic poliomyelitis can be associated with many non-neurologic diseases. A mere listing of these diseases would accomplish little, and there is not space to discuss each one separately. Common respiratory tract infections, particularly influenza, can be particularly puzzling since in both there are general aches and pains, muscle soreness and an alert sensorium. Headache, fever, vomiting and a stiffness of the neck or the back may be detected by the physician who is thinking of the possibility of poliomyelitis. In a somewhat similar manner rheumatic fever can be confusing, since we find headache, pains in the joints which, especially in children, may be interpreted as muscle pains and, when the spine is involved, a stiff neck and back makes a picture strikingly similar to poliomyelitis. As is well known, the onset of many acute febrile illnesses in children is associated with headache and stiff neck and back in a syndrome commonly called meningismus.

If the symptoms lead the physician to decide that a lumbar puncture is indicated, and the spinal fluid shows an increase of cells, the conditions mentioned are promptly excluded, and only diseases with actual involvement of the central nervous system have to be considered. First, in order of importance since specific therapy is available, is purulent meningitis, then parameningeal septic infections and finally other virus diseases of the central nervous system. It is very important to evaluate the sensorium. It is true that in a small percentage of poliomyelitis patients the sensorium is dulled, and there is confusion and apathy. Almost never, however, are there convulsions and seldom deep coma. In purulent meningitis the sensorium is often disturbed markedly, and patients are stuporous if not unconscious, and they frequently suffer convulsions. Ordinarily, therefore, the differentiation is easy even without aid of spinal fluid examination, but much help is obtained from spinal fluid examination in most cases. Mumps meningitis with parotitis and lymphocytic choriomeningitis can give a picture quite similar to that of nonparalytic poliomyelitis, but the usual spinal fluid in mumps with nearly 100 per cent lymphocytes in a total count of several 100's early in the acute disease makes the differentiation easy. Brain abscess or extradural abscesses can cause fever, headache, vomiting, stiff neck and back and spinal fluid changes which may simulate those of poliomyelitis. The more septic nature of the disease and the presence of an otitis or sinus infection greatly aids the differentiation. Purulent meningitis itself usually has a cell count in the thousands with low sugar and the presence of micro-organisms. If from spinal fluid examination we have ruled out mumps and purulent meningitis, we have a variety of other diseases to consider, among which occur with increasing interest the Coxsackie group and some of the so-called ECHO group. It was stated above that ordinarily by clinical or spinal fluid examination no exact differentiation can be made between nonparalytic poliomyelitis and Coxsackie or ECHO virus infections. There are other conditions which cause encephalitis where the degree of involvement of the encephalon or the presence of convulsions can rather certainly rule out poliomyelitis. Often, however, in a patient without coma, convulsion or paralysis, the clinician is unable to make a certain diagnosis of poliomyelitis until eventually he is aided by data from the virus laboratory.

Differential Diagnosis in Disease with Signs of Paralysis. Where paralysis or the resemblance of it is apparent, this symptom becomes the leading point in the diagnostic attack. Paralysis in poliomyelitis may be encountered first in the acute febrile meningeal stage or as an isolated symptom after the febrile period is past. The approach to the differentiation should be made by orderly steps: (1) determination of the actual existence of paralysis instead of a "pseudoparalysis" due to pain, (2) differentiation between upper and lower motor neuron disease, (3) if it is determined that an actual flaccid, lower motor neuron paralysis exists, differentiation from diseases functionally disturbing other parts of the cord as well as the motor

cells; and (4) if only motor lesions occur differentiation from several types of so-called "peripheral neuritis."

Differential diagnosis of the bulbar and the respiratory paralyses need to be considered separately from paralyses of the trunk and the extremities.

Pseudoparalysis of Trunk and Extremities. One group of diseases confused with poliomyelitis, especially in children, is that which produces tenderness of extremities, so that a patient's unwillingness to contract a muscle because of pain may be interpreted as paralysis

Tenderness and a pseudoparalysis which simulates poliomyelitis to the poliomyelitis-conscious physician or parent can be caused by a host of conditions in young children following unreported trauma Scurvy in nonepidemic and epidemic times has been confused with poliomyelitis Syphilis can cause a similar picture in small infants The appearance of paralysis occurs sometimes in Sydenham's chorea, and one extremity may appear limp and flaccid A pinprick will usually make it evident that muscle power is present

Differentiation of Actual Paralysis of the Trunk and the Extremities. Exclusion of Upper Motor Neuron Conditions. Having determined that a paralysis is real and not simulated, the next step should be to determine whether it is spastic or flaccid, that is, whether the lesion is in an upper motor neuron or due to damage to the lower motor neuron Ordinarily, differentiation is easy, but quite commonly the appearance of an upper motor neuron lesion is, for a few weeks or longer in small children, that of a flaccid paralysis, and it is quite difficult to determine the basic mechanism Evidence of increased intracranial pressure, of increased reflexes in other extremities or of eyeground changes often makes a differentiation clear A history of a convulsion preceding the flaccid stage of an upper motor neuron lesion is quite common, and convulsions must be exceedingly rare in poliomyelitis

Exclusion of Other Than Motor Cell Lesions in the Cord. Faced with a flaccid paralysis, one should determine first whether or not there are true and dependable changes in sensation If there is clearly a loss of sensation to touch, to pain, or to position sense, poliomyelitis can be ruled out quickly. The picture of a transection of the cord or transverse myelitis itself is usually quickly distinguished from poliomyelitis by the most gross form of neurologic examination.

Exclusion of Peripheral Nerve Lesions. When all of a nerve trunk is so involved as to prevent its functioning, evidence of sensory nerve distributions may rule out poliomyelitis fairly quickly. When only the motor part of a single nerve trunk is involved, knowledge of the distribution of a nerve is helpful in differential diagnosis It is characteristic for a peripheral nerve lesion that extensively involves an arm or a leg to bring about a paralysis of the fingers and the toes as well as of the great muscles Poliomyelitis, on the other hand, may cause a complete paralysis of the whole extremity except the toes or the fingers

A number of diseases occur which cause lower motor neuron palsies, but all of these conditions cannot be discussed separately. The nomenclature is confused, but multiple neuritis, peripheral neuritis or postinfectious neuritis or neuronitis, and the Guillain-Barré syndrome are favorite terms The coincidence or history of immediately preceding infection with the virus of measles, chickenpox or vaccinia often makes the etiologic agent clear. In general, as distinct from poliomyelitis, the paralysis of these diseases is more diffuse in appearance, obviously progresses over a period of days, and, unless death occurs, final recovery is much more likely to be complete. Lead-poisoning and postdiphtheritic paralysis especially should be considered.

Bulbar or Respiratory Muscle Paralysis. The symptoms produced by paralysis may be misinterpreted, and the existence of paralysis be unrecognized This is particularly likely when respiratory distress or difficulty in swallowing is the presenting symptom of the disease as first seen by the physician

Pneumonia. Although it would seem to differ greatly from poliomyelitis, pneumonia can be confused with respiratory muscle paralysis, when meningismus is present and there is a striking difference in excursion of one side of the thorax The opposite mistake may also be made.

Difficulty in Swallowing. Confusion in diagnosis is quite common when the present-

ing symptom offered by a patient is that of inability to swallow The victims of infantile paralysis, when young, may not at first understand their own difficulty When medical aid is sought belatedly or the disease is rapid in course, the patient may present himself first in a state of coma or semicoma with noisy, interrupted breathing and with obvious and marked respiratory difficulty The condition has been confused with *overwhelming pneumonia* or *sepsis*, the noisy, stertorous breathing suggesting that often seen in moribund patients A key to the proper diagnosis should be apparent, particularly if any consciousness on the patient's part can be detected Usually the patients themselves, unless indeed semiconscious and near death, will show great apprehension or terror When the patient is old enough to recognize his difficulty early in the course of his trouble, or when it is evident from watching a patient try to drink some water that there is inability to swallow, a *foreign body causing obstruction to the esophagus* is apt to be considered, and more than one child with pharyngeal paralysis unfortunately has been subjected to esophagoscopy.

Diphtheria has to be considered when palatal paralysis is recognized The presenting symptom is nasal speech and nasal regurgitation on attempts to swallow The absence of diphtheritic membrane in the throat, of course, does not rule out this condition The knee-kicks in diphtheritic paralysis are lost early, while in the acute stage of poliomyelitis, during which palatal paralysis is encountered, the knee-kicks may be exaggerated, if changed at all from normal In diphtheria, ocular palsy is quite commonly associated with palatal and pharyngeal palsies, while it is rare in poliomyelitis

A *cerebral embolus*, a *brain tumor*, and even a *retropharyngeal abscess* can cause symptoms that can be confused with bulbar poliomyelitis

Encephalitic Type of Poliomyelitis While ordinarily the patient with poliomyelitis is alert, at least when aroused, and quite conscious of what is going on, occasionally we see a patient excessively dulled and stuporous, lying in coma The encephalitic sensorium quite commonly is associated with the bulbar type of paralysis but may occur as well in cases with spinal paralysis or no paralysis at all Here the differential diagnosis lies between poliomyelitis, tuberculous meningitis and all the diseases classified under the term encephalitis

Differential Diagnostic Value of Spinal Fluid Findings. A great number of diseases produce changes in the spinal fluid similar enough to those of infantile paralysis to cause confusion

PURULENT MENINGITIS The spinal fluid of poliomyelitis shows a relatively low cell count Any cell count over 1,000 or any cloudy fluid is due more likely to a purulent meningitis than to poliomyelitis In purulent meningitis the spinal fluid sugar usually is reduced, while in poliomyelitis it is increased or normal Cultures and smears for demonstration of micro-organisms always must be made carefully, whatever the presumptive diagnosis.

TUBERCULOUS MENINGITIS The spinal fluids of poliomyelitis and tuberculous meningitis have the same characteristics except for the sugar content, which in tuberculous meningitis is significantly reduced.

PARAMENINGEAL INFECTION A collection of pus near the meninges, either a brain abscess or an extradural abscess such as those associated with mastoid infections, can produce a spinal fluid identical with that occuring in poliomyelitis

Other Virus Infections of the Central Nervous System. From a study of the characteristics of spinal fluid in the clinical laboratory, no features can be detected which enable one to distinguish with certainty between poliomyelitis and a long list of other virus diseases which can affect the central nervous system, such as measles, chickenpox, vaccinia encephalitis, equine encephalitis, St [illegible] encephalitis will produce a characteristic spinal fluid change, when the total count is high, with such a high percentage of lymphocytes that one would consider it incompatible with poliomyelitis

SYPHILIS There are no characteristics of the spinal fluid, excepting the serologic tests (Wassermann, Kahn, etc.), which distinguish syphilis from poliomyelitis

MULTIPLE PERIPHERAL NEURITIS OR NEURONITIS In most cases of toxic neuronitis, Guillain-Barré syndrome, or infectious polyneuritis, only an increased globulin value is found, although rarely a small increase of white cells occurs In lead-poisoning counts as high as 100 or 200 cells are sometimes found Of course, similar spinal fluid findings occur after the acute febrile course of paralytic poliomyelitis.

Poliomyelitis With a Normal Spinal Fluid Can acute poliomyelitis occur with no abnormalities in the spinal fluid? There certainly can be infection with the virus of poliomyelitis without involvement of the central nervous system, but can the disease attack the central nervous system violently enough to produce paralysis and still produce no changes in the spinal fluid? This must be possible However, there often can be a simple explanation for the findings of a negative spinal fluid in the acute stage of the clinically recognizable disease A negative spinal fluid can be obtained if lumbar puncture is done too early, within a few hours of the onset of meningeal symptoms, and also too late, as in some instances the cells apparently disappear very early.

All cases cannot be so explained, nevertheless, we must conclude that it is possible, though rare, to find a normal spinal fluid during the acute state of poliomyelitis in a patient with evidence of paralysis However, great caution must be exercised in making a diagnosis of poliomyelitis under these circumstances

TREATMENT

There is no specific treatment for the disease Stated differently, we can say that no form of therapy now known seems to influence the course of action of the virus on the central nervous system once the virus has entered nerve cells Although the history of poliomyelitis is filled with therapeutic adventures toward direct therapy, there is no good evidence that actual damage to anterior horn cells, which is the specific lesion that makes this disease important, is prevented by any procedure now known A short review of some of the better-known therapeutic efforts in the past seems to be justified.

TREATMENT WITH HUMAN "IMMUNE" SERUM

The demonstration of poliomyelitis antibodies in the blood of human convalescents was recognized early as offering a possible mode of treatment. Accordingly, extensive experiments were carried out with pooled convalescent serum and human adult serum given to patients in the early preparalytic stage of poliomyelitis Hundreds of patients were so treated, and the results furnished a classic example of the hazard of clinical studies of poliomyelitis without proper controls. It was first found that a great deal less paralysis occurred in patients treated with convalescent serum in the preparalytic stage of poliomyelitis than was found in patients who were not so treated but were diagnosed first because of paralysis (Aycock et al, *1929*, Harmon, *1934*). When finally studies were made treating only alternate patients diagnosed in the preparalytic stage, no significant difference in the degree of paralysis that later developed was observed (Kramer et al, *1932*; Park, *1932*) Later studies with gamma globulin (Bahlke and Perkins, *1945*) have also shown no beneficial results in therapy after central nervous system involvement.

TREATMENT BY PROCEDURES DIRECTED TOWARD THE CIRCULATION IN THE CORD

As discussed in Chapter 23, a striking feature in this disease is the perivascular infiltration of the cord with lymphocytes From this it was argued that the damage to the nerve cells themselves was due to anoxia or some other effect resulting from reducing the circulation to the anterior horn cells. Accordingly, therapeutic efforts were directed toward preventing or dispersing the collection of cells around blood vessels of the cord and toward reducing the edema of the brain and the cord Repeated or continuous drainage of spinal fluid was recommended Hypotonic solutions were administered parenterally, and large amounts of water were given by mouth while continuous spinal drainage was maintained Hypertonic fluids were administered intravenously to reduce the edema Adrenalin was given intraspinally All these methods had eloquent advocates, with striking results re-

ported in very small and uncontrolled groups of patients Treatment with both hypotonic and hypertonic solutions has received equally enthusiastic support Since no well-controlled studies of any of these methods of therapy have been presented, we are forced to look on all these efforts as rather desperate attempts to "do something" The concept, so clearly developed by Bodian, that the virus first attacks the great motor cells and that the edema and perivascular infiltration are only secondary, destroys the logic of such treatments It is still quite possible, however, that the secondary interstitial changes may exaggerate the damage produced by the virus, and attempts at a more critical evaluation of such methods of therapy still may be justifiable

Concepts as to the nature of paralysis and its treatment that were considerably different from what had been customarily accepted in the past were advocated by Elizabeth Kenny of Australia and her disciples (Pohl and Kenny, 1943, Pohl, 1945) Greater emphasis was placed on the heat treatment of tender muscles during the acute stage, not simply to relieve pain but as a procedure actually preventing paralysis Immobilization by casts and splints was discarded Muscle re-education with active participation by the patient was begun early in the disease as soon as muscle tenderness, relieved by the hot packs allowed it

Miss Kenny and her followers made broad claims for the efficacy of such treatment These claims reached the public, and her method of treatment was carried out widely There was much that was good in the treatment, but the explanatory theories were poorly founded They taught that there was actually no true paralysis, as it is ordinarily understood in poliomyelitis, but that all paralysis resulted only if tenderness and spasm were not reduced or eliminated by the use of hot packs applied in a very specific manner Their explanation of the physiologic disturbances in poliomyelitis hardly deserves more discussion However, the effectiveness of the Kenny school in muscle re-education almost balances in good the lack of sound theory and the devotion to certain unimportant details

Unfortunately, as has been true with other adventures in therapy, attempts at treatment of the paralysis of poliomyelitis have been carried out without proper control studies, without proper muscle examination, and apparently with a great lack of experience and knowledge as to what happens in the natural course of the untreated disease Since, even with the most meticulously careful muscle examinations, a good number of all patients [illegible]

can be seen how easy it is to give credit to any form of therapy that is generally applied without carefully planned controls during the acute stage of the disease Much of the apparent paralysis is transitory and, moreover, when pain or spasm exists, it is extremely difficult to differentiate true paralysis from muscle inhibition due to pain It has long been noted that improvement in muscle function takes place over periods of months and years It is hard to determine how much of this has taken place by nature alone and how much has been effected by treatment of some sort that has been carried out, but a certain amount of improvement always takes place no matter what the treatment Sudden, almost dramatic, improvement has occurred and has been reported at various stages, sometimes after periods of months, both with no treatment and after some particularly well-advocated treatment Obviously, no form of therapy in this disease can be accepted as effective unless one critically evaluates it in the light of the spontaneous variations which may take place

General Therapeutic Measures

Rest. Excellent studies strongly suggest that the value of rest in the preparalytic and the early paralytic state of poliomyelitis may be more specific and considerably greater than we are apt to consider it in other diseases, and that activity or rest may actually make the difference between permanent destruction and temporary incapacity of certain nerve cells The evidence supporting this idea is derived from the observation that many patients with the worst paralysis gave a story of continuous activity, sometimes violent, during the very early hours or days

of the disease. It is not apparent that exercise during the incubation period or the "dromedary" period is of importance The ill effects of such activity have been supported by several good studies (see above). It seems justified to make every effort to insist that absolute rest be carried out at the first sign of illness due to poliomyelitis or, in epidemics, at the first symptom of any undiagnosed febrile illness. This is good theory but often hard to put into practice without frightening the public

Fluids. Fear is often expressed of giving too much fluid, particularly parenterally, to patients suffering from edema of the medulla. The tendency of inflammed tissues to give up fluid less readily and take it up more readily seems to be established, and a reasonable program should make a compromise between overhydration and dehydration, therefore, a moderate amount of fluid with consideration for the patient's fever and sweating and, most of all, his comfort, should be allowed

Care of the Skin. These patients sweat profusely and are partially immobilized both by tenderness and actual paralysis Care of the skin is further complicated by the application of hot, wet packs to tender muscle groups. Especially careful nursing attention must be given

Comfort. Patients with poliomyelitis may suffer much pain The treatment of muscle tenderness with heat is discussed below The physician must be particularly concerned in directing the nursing of infants and small children, who may be handled by their attendants without any proper understanding of the degree of pain that is caused Attempts to evaluate paralysis by the doctor, changing of diapers and other routine procedures by the nurse should be carried out with the greatest gentleness

Intestinal Stasis. Disturbance in the function of the intestine and paralysis of the bladder need particular attention during the acute stage of the disease. Constipation is marked in many patients and probably is at least partially due to a disturbance of peristalsis brought about by the disease Intestinal stasis is temporary and lasts only a few days, but abdominal pain due to the constipation should be relieved by small enemas gently administered.

Urinary Retention. Bladder paralysis also seems to be temporary, but few careful follow-up studies have been made. Relief may be obtained by catheterization after it has been demonstrated that the patient cannot void spontaneously. The risk of catheterization is justified by the marked urinary retention and the pain which otherwise would occur Usually 2 or 3 catheterizations will be enough to carry the patient over this phase of his disease.

Treatment of Paralysis

There is no specific treatment for the paralysis, but many nonspecific steps may make important differences in the final outcome The treatment of paralysis caused by poliomyelitis will not be discussed in this chapter at any great length. The complex details involved in immobilization of paralyzed muscles, different types of physiotherapy, muscle training and surgery with its various corrective and stabilizing operations are too specialized for proper consideration here. Certain simple principles of treatment may be outlined, although at the risk that oversimplification may lead to inaccuracies. Most orthopedists agree on the following general procedures:

1 Protection of paralyzed muscles to be effected by suitable splints, casts or other means of fixation for the period of muscle tenderness or spasm which may last several weeks. This should not be carried to extremes, and motion up to the point of pain only should be permitted.

2. The application of heat during the acute stage to tender muscles by the use of hot packs. This has been emphasized always as important for comfort, if not for any specific effect on the course of the disease that might result

3 The cautious initiation of physiotherapy technics for the stimulation and the re-education of weakened muscles and prevention of contractures, always carried out to a point short of fatigue, with immobilization being reapplied in the hours of the day not given over to such physiotherapy.

4 During a final stage, after most muscle function has returned that will return, the use of muscle transplant and stabilization operations on the joints to permit the most efficient function of residual muscle power.

The relief of pain in the acute stage by the use of hot packs applied sensibly in moderation over a limited number of days or weeks and on the basis of definite subjective relief is generally accepted. There has been a great reduction in the use of immobilization technics, and opportunity is given the patient to move around in bed and to use partially paralyzed muscles to the limit of his desire, short of fatigue and pain Gradual attempts at passive motion and muscle re-education are accepted as of very great importance The technic of muscle re-education requires specially skilled technical workers with a good knowledge of functional anatomy and a personality that can induce a timid patient consciously to endeavor to use each muscle Undoubtedly, great improvement in function takes place as a result of skillful muscle reeducation, not only in poliomyelitis but also in many other conditions whether or not associated with pain Ultimately, the use of supporting braces, splints or stabilizing operations to allow the patient to make whatever use he can of what muscles he has left is of great importance.

Treatment of Paralysis Leading to Respiratory Failure

The manner in which poliomyelitis may lead to respiratory failure has been described above The successful treatment of respiratory difficulty in poliomyelitis depends upon an exact clinical analysis of the functional defect Although we can no more prevent the poliomyelitis virus from causing bulbar or respiratory paralyses than we can prevent it from causing paralyses of arms or legs, nevertheless, even symptomatic treatment may make the difference between life and death in the forms of poliomyelitis that may lead to respiratory failure Even so, too often at autopsy the extensive destruction of the brain stem with its "vital" centers demonstrates the futility of any form of treatment now known.

Although elaborate programs have been outlined for the treatment of the complex conditions leading to respiratory failure, only the relatively simple procedures are surely effective Furthermore, although there are frequently multiple palsies in the individual patient, the different effects must be untangled and a logical program directed toward the difficulties as they present themselves Therefore, we must consider separately respiratory distress from respiratory muscle paralysis, from pharyngeal paralysis, from "central" disturbance of respiratory control, and their combinations

Signs and Symptoms. The early symptoms of respiratory involvement result from increased respiratory effort rather than from actual respiratory failure Many attempts have been made to use elaborate laboratory methods for the early detection of respiratory insufficiency, specifically, the determination of oxygen saturation levels of hemoglobin and of blood carbon dioxide levels However, in spite of respiratory muscle weakness, increased effort in breathing may be successful in maintaining normal or even increased alveolar ventilation Therefore, neither of these determinations nor any other blood chemical measurement now available is likely to prove useful in detecting early respiratory weakness and, in fact, may be misleading (Dickinson et al, 1953) Determination of the reduction of vital capacity, especially in adults, is helpful, but in the absence of predetermined levels of the patient's normal capacity, early and moderate reductions may not be detectable

Many patients with acute poliomyelitis, either with or without moderate degrees of respiratory muscle weakness, succeed in breathing with such effort that actually overventilation of the lungs, leading to alkalosis, results This probably is due to anxiety and fear Hyperventilation, in our experience, is more characteristic of early respiratory muscle weakness than is actual failure of respiratory effort (Dickinson et al , 1953)

In order of likely sequence, we regard the following as clinical signs first, of increased respiratory effort, and then of respiratory insufficiency

Increased Respiratory Effort

1 Increased rate of breathing
2 Dilatation of nostrils
3 Interruption of speech
4 Use of accessory muscles of respiration

Effort and/or Failure

5 Anxiety
6 Restlessness or sleeplessness
7. Disorientation

Respiratory Failure

8 Coma
9 Cyanosis
10 Convulsions

Anxiety, restlessness and disorientation may be evidence not only of effort or fatigue but also of actual failure of respiratory function, that is, of hypoxia or carbon dioxide retention Coma, cyanosis and convulsions can surely indicate respiratory insufficiency, easily shown by carbon dioxide determinations or oxygen saturation levels of hemoglobin but usually long after the clinical signs of dyspnea are clearly evident Furthermore, disorientation may be the result of fatigue alone as well as of carbon dioxide retention or oxygen lack However, such fatigue may lead soon to respiratory inadequacy Cyanosis is likely to be an agonal symptom unless for short periods due to remediable airway obstruction

A valuable early sign of respiratory effort and reduction of vital capacity is interrupted, staccato speech It is quite characteristic to hear a patient speak with only several syllables to each breath.

Demonstration of a moderate degree of paralysis of the diaphragm or of the intercostal muscles can be aided if dyspnea is caused or made greater by splinting the chest or the abdomen by one's hands.

Respiratory Muscle Paralysis One could consider the use of the respirator for respiratory paralysis as desirable not only to save life in extensively paralyzed patients who would otherwise die but also to give rest to those partially paralyzed patients with only slight dyspnea The relief to the latter patients is often far more striking than would be expected Not infrequently, symptoms of mental confusion due to anoxia or accumulative fatigue may be relieved when the patient is given respirator treatment, in spite of the fact that it was not obvious that the muscles of respiration were severely paralyzed.

An original justification for the use of the respirator in severely stricken patients rested wholly upon the possibility that eventually the respiratory muscles would improve If improvement could not take place to an extent allowing the patient eventually to become independent of such a device, and if the respirator treatment only led to a persistence of this tragic situation, its use could hardly have been justified. However, experience has taught that no absolutely bad prognosis for recovery can be so certainly made that withholding the use of the respirator at the time when its use is first indicated can be justified. Some degree of recovery almost always occurs, and occasionally very remarkable return of function is evident. It is logical to use such aids to respiration in early respiratory muscle paralysis whenever they provide rest and comfort and are not themselves a cause of persistent anxiety and fear.

Luckily, even in badly paralyzed patients, control of alveolar ventilation is not wholly lost, so that a reasonably efficient regulation of respiration can be maintained by rough adjustments of pressure and rate possible in these machines.

Besides the standard tank respirator, the cuirass type respirator and the Rocking Bed, and the various positive pressure devices are useful None is so efficient and dependable that it can well be substituted for the tank respirator early in the course of extensive respiratory muscle paralysis, but these devices are of great aid in weaning patients from the tank respirator.

The time for initiating respirator care cannot be stated arbitrarily because the patient's emotion influences the decision If, in spite of proper psychologic preparation, he is greatly frightened by this coffinlike machine or any other mechanical equipment, especially applied over the mouth, he may prevent its early effective use, even if it does give him some rest. Often only a trial of the machine will determine whether or not it will be effective.

Respirator Addiction. One of the most puzzling problems in the care of patients in a respirator, particularly with emotionally labile people, and probably more with adults than with children, is addiction to the respirator or overdependence on it. As mentioned above, hyperpnea, alveolar overventilation, is also seen before any mechanical device for the aid of respiration has been used, and this phenomenon seems to be due to fear Therefore, the word "addiction" may not always be appropriate, since the habit of overventilation was established before dependence upon

artificial respiration could have developed However, persistent hyperventilation establishes an abnormal pH and arterial pCO_2 Renal compensation may then return the pH to normal, after which continued hyperventilation becomes necessary to maintain a normal pH This might be considered as physiologic addiction.

Adjustment of the Respirator We cannot hope here to detail directions for running a tank respirator for the care of a patient with respiratory muscle paralysis Let us say, however, that the task is not as difficult as it might first seem Usually a rhythmical negative pressure of 15 cm of water at a rate of 16 to 20 a minute is adequate for normal gas exchange. When the respirator was invented it was with considerable trepidation that it was first used in fear that with such a crude instrument the marvelously delicate maintenance of balanced pulmonary ventilation that the body regulates never could be approached and that we would be constantly in the position of producing acidosis or alkalosis However, it became clear that few patients are fully paralyzed and that most can control their respiration to a certain extent The closing of the glottis can prevent overventilation to a certain degree if the patient chooses to do so, and usually he can aid inspiration We have already emphasized the psychic disturbance which leads to overventilation, and the physiologic disturbance which continues a tendency toward overventilation However one can hardly have a constant blood oxygen or alveolar pCO_2 analysis recorded on the patient Even if these data were available, it might not be a good guide as was explained earlier A good clinician can learn much by simply watching his patient, particularly when the patient is asleep or unaware that his respiration is being studied A patient with inadequate pulmonary ventilation, or at least one not satisfying his requirements, whether or not they are normal requirements, will show some dilatation in the alae nasae or he may show use of his accessory respiratory muscles in the neck or may take extra breaths between those the machine initiates This should be an indication to step up the rate or the pressure of the machine If the patient is overventilated and has not accepted it, he may close his glottis, causing a noise of inspiratory obstruction, or one may notice a contraction of the abdominal muscles during the inspiratory phase of the machine, which is very revealing if one looks for it. These clinical guides are sound and should not be neglected in this age of blood chemistry

Pharyngeal Paralysis In treating any patient with pharyngeal paralysis, aspiration of the secretions from the throat frequently is of lifesaving value, and suitable apparatus for accomplishing this always should be at hand Careful attention should be given, when motor-driven suction is available, that too great suction does not traumatize the mucous membranes As little aspiration should be carried out as is necessary to keep the patient comfortable, as in certain excitable patients the procedure may irritate the pharynx, increase the apprehension of the patient and so increase the production of mucus In some patients such great relief is afforded by aspiration that they request it and sometimes can carry it out themselves In children much tact and reassurance, particularly at initiation of treatment, is necessary A metal aspirator tube that can be placed in the throat exactly where it is needed is most effective A rubber tube, although it seems soft and least likely to be traumatic, often cannot be directed effectively and will increase the gag reflex if it touches the postpharyngeal wall

Atropine, used to dry up secretion, does more harm than good It may result in the production of thick, sticky secretions which are even more difficult to remove, and the effect of atropine itself on the rate of the heart in bulbar poliomyelitis should be avoided

The handling of the excitable and nervous patient needs special emphasis Anxiety and fear of choking make patients with pharyngeal paralysis much more difficult to treat The more frightened they become the more the secretions bother them and the greater their fatigue becomes so that aspiration of the throat can be carried out only with such a struggle as greatly to diminish its value A calm, reassuring attitude, deliberate and firm action on the part of the doctor and the nurse, and the avoidance of a state of confusing bustle and hurry are of crucial importance.

In spite of the greatest skill by nurses and physicians in preventing aspiration into the lungs and in keeping the pharynx free of secre-

tions, success will not always follow. Although in many cases of pharyngeal paralysis it can be avoided, a tracheotomy to produce a free airway and allow sleep has been advocated for many years in certain patients (Wilson, 1932), particularly in the high-strung, nervous type. Since this time, especially in the last 8 years, much more experience and enthusiasm in the use of tracheotomy has been reported (Glaser, 1945, Brown and Baker, 1949). One of the best studies was by Plum and Dunning (1956). An acute attack of cyanosis due to choking on aspirated secretions or vomitus seems seriously to aggravate the underlying pathologic condition, at least, after such an attack patients are often dramatically and permanently worse. It seems quite possible that generalized hypoxia has a direct effect on the course of the disease in the central nervous system The use of tracheotomy to prevent such a situation is therefore clearly indicated The problem is to carry out the tracheotomy before an acute attack of cyanosis makes it obvious to everyone that it should have been done earlier and yet not make the procedure so routine that many unnecessary tracheotomies are done It requires good judgment and careful observation to determine this point A tracheotomy is a serious and mutilating operation and is a step not to be undertaken lightly Unfortunately, tracheotomy has been advocated with such enthusiasm that many practitioners believe ill-advisedly that it is indicated for all cases of "bulbar" poliomyelitis, or worse, for all respiratory distress

The need for this operation usually can be determined by a few hours of critical observation The emotional attitude of the patient, his response to aspiration, postural drainage and oxygen therapy can give one a good idea of the need for tracheotomy before one gets into great difficulties One should demand that a patient under a conservative method of care should be able to get such relief that he can relax and go to sleep If he cannot relax, if sleep is constantly interrupted, the condition will get progressively worse, since fatigue will greatly prejudice the chances of a successful outcome, and tracheotomy is clearly indicated.

Sometimes it is extremely difficult to determine whether the irregular respirations are due to pharyngeal secretions or to damage to the respiratory centers themselves in the brain stem. If the respiratory disturbance is central in origin, a tracheotomy does not seem to be logical unless artificial respiration is indicated because the patient's own efforts are ineffective. However, it is often difficult to make a clear distinction as to which is causing the symptoms and, if uncertainty exists after careful observation, the operation is justified.

In the last 4 or 5 years the use of positive pressure breathing devices, attached to a tracheotomy tube, have been increasingly valuable. The widespread use of this in Europe followed from the studies of Scandinavians (Engstrom, 1954). A tracheotomy tube with a cuff which made an airtight connection in the trachea was generally used, so that full control of respiration was given over to the machine. Although much has been learned by the development of these devices, one could question whether their use was as wise as was first thought. Tracheotomy apparently was used very indiscriminately for all patients with respiratory distress. In this country more conservative use of positive pressure devices with a tracheotomy has developed and undoubtedly has been lifesaving Positive pressure respiration, without an airtight tracheal connection, has become extremely useful (Morch et al, 1956). This is particularly true in patients who have to have tracheotomy anyway and in whom the tracheotomy is not indicated simply to make it convenient to give positive pressure respiration when other devices could be used Cumbersome as it is, the use of the tank respirator seems to be far wiser except where a tracheotomy is indicated for pharyngeal paralysis or loss of central control The disadvantage of a tracheotomy with an airtight cuff to the trachea is that the constant pressure leads to ulceration and hemorrhage in some cases, though the first advocates of this technic themselves do not look on this risk as serious. Although undoubtedly the greater use of tracheotomy has saved lives and is amply justified, the great disadvantage is the trouble in eliminating it once it has been used, and particularly after use for some time. There is not only the psychic problem in getting rid of the tracheotomy too, which is reminiscent of the

problem of getting the patient out of the respirator, but there is a real pathologic problem in the risk of inflammatory processes in the larynx which causes laryngeal obstruction as well as the chronic inflammatory condition in the trachea itself The mechanical disadvantages of taking care of a patient with a tracheotomy who must also be in a tank respirator are great, though the problem has been managed successfully many times The care of a patient outside of a tank is obviously much simplified

Laryngeal Paralysis. Laryngeal paralysis can be quickly lethal if it involves the abductor muscles bilaterally by obstructing the airway through the larynx Warning signs are hoarseness or aphonia. Tracheotomy is the only effective treatment In an emergency, the insertion of an intratracheal tube through the pharynx may be life-saving until a tracheotomy can be performed

Involvement of the Respiratory Centers. When the respiratory centers are involved, death from respiratory failure can occur with a patent airway and normal respiratory muscles, because the co-ordinated drive for breathing has been lost Such patients breathe very irregularly, they characteristically take a deep breath followed by several ineffectual breaths and may have frequent periods of apnea They are more apt to breathe effectively though irregularly when stimulated, only to become cyanotic and apneic when left alone or when they fall asleep These patients, in contrast with those with respiratory muscle paralysis or airway obstruction, can develop actual respiratory failure and die with no signs whatever of dyspnea. They are usually completely unable to synchronize with a mechanical respirator, although such treatment may be lifesaving because the machine converts an occasional small ineffectual breath into an effective one.

Several years ago the electrophrenic respirator was devised for this type of patient (Sarnoff et al, 1948, 1950) By completely blocking the inefficient, irregular efferent impulses from the malfunctioning respiratory center and by providing artificial rhythmic stimuli, this device produces completely controllable respirations However, it requires a normal phrenic nerve In our experience it is the rare patient indeed who is helped by its use.

Recently, a number of physicians have suggested that the patient with a malfunctioning respiratory center who is unable to synchronize with a mechanical respirator may be saved by administering one of the purified curare preparations to paralyze the respiratory muscles completely, after which he can be "breathed" with a mechanical respirator without difficulty. We have had no experience with this technic, but it seems logical and certainly deserves further study. Many years ago, in fact, in the first year a tank respirator was used, some success in this problem was achieved with the use of morphine in place of curare, although it was realized then that a "pure" curarelike action might be useful (Wilson, 1932)

Pulmonary Edema Pulmonary edema is a grave complication requiring emergency treatment. The mechanism of its production during acute poliomyelitis is still not clear. There is experimental evidence supporting the theory that involvement of certain portions of the midbrain may be primarily responsible This complication, when it arises, is always life-threatening, although it rarely lasts more than a few hours in those patients who survive Oxygen should be administered under pressure, either by face mask or tracheotomy tube attachment. If the patient is in a tank respirator the negative pressure should be increased to maximum. If signs of cardiac failure are present, standard treatment, including parenteral digitalization, is indicated If the patient has a tracheotomy, some physicians believe that a few drops of ethyl alcohol instilled directly into the trachea will decrease the foaminess of the edema fluid and allow better alveolar gas exchange

Hypertension. Mild hypertension fairly commonly accompanies poliomyelitis in the acute and early convalescent stages Its causes are still in dispute but are probably multiple Rarely, paroxysms of extremely severe hypertension are encountered These can be treated symptomatically with one of a number of autonomic blocking agents. However,

tions, success will not always follow. Although in many cases of pharyngeal paralysis it can be avoided, a tracheotomy to produce a free airway and allow sleep has been advocated for many years in certain patients (Wilson, 1932), particularly in the high-strung, nervous type Since this time, especially in the last 8 years, much more experience and enthusiasm in the use of tracheotomy has been reported (Glaser, 1945; Brown and Baker, 1949) One of the best studies was by Plum and Dunning (1956). An acute attack of cyanosis due to choking on aspirated secretions or vomitus seems seriously to aggravate the underlying pathologic condition, at least, after such an attack patients are often dramatically and permanently worse. It seems quite possible that generalized hypoxia has a direct effect on the course of the disease in the central nervous system The use of tracheotomy to prevent such a situation is therefore clearly indicated The problem is to carry out the tracheotomy before an acute attack of cyanosis makes it obvious to everyone that it should have been done earlier and yet not make the procedure so routine that many unnecessary tracheotomies are done It requires good judgment and careful observation to determine this point A tracheotomy is a serious and mutilating operation and is a step not to be undertaken lightly Unfortunately, tracheotomy has been advocated with such enthusiasm that many practitioners believe ill-advisedly that it is indicated for all cases of "bulbar" poliomyelitis, or worse, for all respiratory distress.

The need for this operation usually can be determined by a few hours of critical observation. The emotional attitude of the patient, his response to aspiration, postural drainage and oxygen therapy can give one a good idea of the need for tracheotomy before one gets into great difficulties. One should demand that a patient under a conservative method of care should be able to get such relief that he can relax and go to sleep If he cannot relax, if sleep is constantly interrupted, the condition will get progressively worse, since fatigue will greatly prejudice the chances of a successful outcome, and tracheotomy is clearly indicated.

Sometimes it is extremely difficult to determine whether the irregular respirations are due to pharyngeal secretions or to damage to the respiratory centers themselves in the brain stem. If the respiratory disturbance is central in origin, a tracheotomy does not seem to be logical unless artificial respiration is indicated because the patient's own efforts are ineffective However, it is often difficult to make a clear distinction as to which is causing the symptoms and, if uncertainty exists after careful observation, the operation is justified.

In the last 4 or 5 years the use of positive pressure breathing devices, attached to a tracheotomy tube, have been increasingly valuable The widespread use of this in Europe followed from the studies of Scandinavians (Engstrom, 1954). A tracheotomy tube with a cuff which made an airtight connection in the trachea was generally used, so that full control of respiration was given over to the machine Although much has been learned by the development of these devices, one could question whether their use was as wise as was first thought Tracheotomy apparently was used very indiscriminately for all patients with respiratory distress In this country more conservative use of positive pressure devices with a tracheotomy has developed and undoubtedly has been lifesaving. Positive pressure respiration, without an airtight tracheal connection, has become extremely useful (Mörch et al, 1956). This is particularly true in patients who have to have tracheotomy anyway and in whom the tracheotomy is not indicated simply to make it convenient to give positive pressure respiration when other devices could be used. Cumbersome as it is, the use of the tank respirator seems to be far wiser except where a tracheotomy is indicated for pharyngeal paralysis or loss of central control The disadvantage of a tracheotomy with an airtight cuff to the trachea is that the constant pressure leads to ulceration and hemorrhage in some cases, though the first advocates of this technic themselves do not look on this risk as serious Although undoubtedly the greater use of tracheotomy has saved lives and is amply justified, the great disadvantage is the trouble in eliminating it once it has been used, and particularly after use for some time There is not only the psychic problem in getting rid of the tracheotomy too, which is reminiscent of the

acute phase of the disease and in early convalescence, but after weeks and months of this apprehensive, meticulous protection and isolation it is little wonder that some patients lose all incentive to live and families gradually drift away. Although convalescent polio patients may be severely handicapped physically and indeed some may be in a dangerous situation, they are not usually "sick" in the traditional sense of the word, and they need the stimulus of active and competitive living far more than the peace and the quiet of a standard hospital environment Where it is possible (see Respirator Centers) we believe that it is desirable to group as many as 10 or 20 patients in a single large room For the past several years we have mixed men, women and children in the same room without evidence of embarrassment and with clear evidence of the benefits gained by community living The patients are encouraged to wear slacks or shorts and sport shirts rather than the traditional hospital pajamas Standard beauty services should be available and used Visiting hours should be unlimited, except for short rest periods, in order to reestablish close family ties and to familiarize relatives with the details of necessary patient care Individual gains can be publicized, and the patient finds that, for the first time, he can compete on an equal basis with at least a few other people who have similar problems The patients also soon realize that they are not, and cannot be the center of attention They realize that there are other problems besides their own and that occasionally they must wait to get what they want It is also healthy, within limits, for a patient to learn to tolerate the activities of others even when these activities are annoying to him In other words, the willing acceptance of some irritating factors in his environment is essential for the mental attitude which enables a patient to strive aggressively to become again a useful citizen

Care of Patients with Maximum Paralysis in Respirator Centers. The long-time care of the severe paralytic patient is too complex a problem to be dealt with here in any detail, but a brief report of the development of the so-called Respirator Centers for the care of some of these patients is necessary

It became evident in the last 8 to 10 years that [illegible] the [illegible] with [illegible] lytic disease, had left in its wake a large number of terribly handicapped patients, living a life under practically custodial care in many hospitals, dependent upon this apparatus for their survival Accordingly, with aggressive action and money of the National Foundation for Infantile Paralysis, some 15 Respirator Centers for the care of these most terribly crippled patients were developed in the country Most of these patients not only had extensive paralysis of their respiratory muscles but also of their arms and legs It was evident that the mechanical respirator saves lives indeed, but often a life not worth saving unless some degree of self-sufficiency and independence can be developed It soon became apparent that much could be done even for the most tragically crippled patient The result of the work and the actions in these centers has been that a great many patients have been freed from immobilizing "respirator" care and have been returned to a life in their homes and often to useful occupation As an example of the last success, one center can report that of some 60 patients who had previously earned a living, 41 were returned to honest income-producing work even though some of them still required respiratory assistance The purpose of the centers, therefore, was (1) to free patients from respiratory assistance, particularly the immobilization of the tank respirator, (2) to return them to home life with continued medical and technical supervision when necessary, and (3) to give them assistance so that they could become useful or income-producing and, at the very least, care for themselves

There follow brief comments outlining the procedures for freeing a patient from immobilizing dependence on mechanical equipment

The respirator patient faces 3 handicaps

1 Most easily understood is the actual reduction of respiratory muscle capacity with resu[illegible]

2 [illegible] tion

reduction in elasticity of the thorax and the lungs and thus an increased resistance to expansion

preceded by a short period (from 30 minutes to 6 hours) of hypertension, and specific treatment of the hypertension with hypotensive drugs would be strongly contraindicated in these patients However, recurrent paroxysms of severe hypertension may in themselves be life-threatening and should be treated

Shock. The exact physiologic definition of shock is not agreed upon, but arterial hypotension seems to be a crucial factor. We know of no very effective method of treating "shock" occurring in acute poliomyelitis The majority of patients who develop cardiovascular collapse will die in spite of attempts at therapy However, some do survive, and the following measures are traditional and may be lifesaving. If the patient is in a tank respirator, the pressure setting should be altered so that approximately equal positive and negative pressures are used, thus helping to restore the normal filling pressure gradient in the right atrium. A few workers report favorable results from the use of norepinephrine by continuous intravenous drip Initial administration should be accompanied by almost continuous blood pressure measurements and the rate of administration adjusted to produce the desired blood pressure

Emotional Disturbance. The subject of treatment cannot be ended without some discussion of the care of the emotional disturbances which have been mentioned in general above The fact that severe emotional disturbances occur is very clear and does not seem difficult to understand. The physician must be aware that in part the widespread understanding and knowledge of the disease poliomyelitis and its well-advertised risks is going to cause a far greater fear of this disease than any other, except perhaps cancer. Immediately the diagnosis is entertained or made, some explanation must be given to any person of reasonable maturity that the degree of paralysis is by no means always great and that even when paralysis occurs, there may be a great deal of spontaneous recovery. The experience in handling badly paralyzed patients, particularly in our respirator centers, is great but does not lead to any possibility of a simple handling of the subject. Contacts of one patient with another equally seriously handicapped who has made considerable recovery and is accomplishing something with the aid of rehabilitation technics works wonders It was learned early in the respiratory centers that if the patients were together in one open ward the new victims were greatly encouraged by the progress that they could see made in their neighbors who had suffered the condition longer. Real hope given to a patient confined in a tank respirator that someday he can become independent even though handicapped, that he probably can be useful and even earn his own living, is the best form of therapy. The physician can help matters at the very beginning of the illness, particularly when it is apparent that the paralysis is going to be severe, by making the family also realize that they must keep a place for the patient in the home Often, when elaborate attempts at rehabilitation have been more or less successful, one finds the tragic situation that the home in the meanwhile has become closed. During the long periods of hospitalization, when the family did not really expect the patient to return, his place and space in the family life became occupied by another. This usually can be prevented Although suffering cannot be completely prevented by any means, a bad situation can be prevented from becoming worse if the physician is alert to the emotional consequences of the disease on the patient and his family at the onset of the disease.

Treatment of Emotional Problems Much can be done to foster good emotional hygiene in a convalescent poliomyelitis patient. Too often severely involved polio patients have been kept for months in quiet, private rooms, completely cut off from activities not essential for their immediate medical care Frequently, the patient's husband or wife may be able to visit for only an hour a day or perhaps only once or twice a week Often he is not allowed to see his children for months on end. Relatives are afraid to touch him or get near him for fear that something will happen and he will die The major emphasis is on immediate medical treatment, with any discussion of rehabilitation limited to general terms and projected to the future "when he gets better." Polio patients need the peace, the quiet, the sympathy and the protection from numerous visitors during the

and mice were susceptible to infection by poliomyelitis virus This discovery furnished far less expensive animals to work with, and quantitative studies of virus distribution and of antibodies could be undertaken Another important advance occurred when the chimpanzee was recognized as an animal which reacted most nearly like the human being and could be infected by oral administration of the virus.

Finally came what seems to be the greatest forward step of all, when the tissue culture technic for the study of poliomyelitis virus was made available by the studies of Enders and his associates (1949), so that really quantitative work could be carried out a hundred times more easily than in the early studies.

In the countries with the poorest sanitation, perhaps most of the inhabitants are infected very early. However, it is important to understand that the disease as we recognize it with its paralytic consequences occurs only rarely in these infections. To repeat, the paralytic disease is a rare complication of poliomyelitis virus infection

The natural spread of the virus in countries with poor hygiene is probably through the stools Most infants are infected in the early months of their lives when antibodies, transmitted from their mothers, still protect them so that they acquire active and permanent immunity during this safe period of passive immunity The disease is thus rare and is true "infantile paralysis" in primitive countries Only in more civilized countries in the last 50 years has the disease become epidemic, and during this period the total incidence of the disease has greatly increased During the same time the age incidence has shifted so that it is no longer truly "infantile" paralysis but a disease of children and young adults Table 14 indicates the reported incidence of the disease, but it must be remembered that such reports may be inaccurate (1) that mild cases are frequently missed, and (2) that nonparalytic poliomyelitis which swells the total reported incidence may not have been poliomyelitis at all but infection with some other virus (see Diagnosis).

In countries where epidemics occur, the virus is found to be widespread during these times, but it is not indiscriminately spread and is to be found more readily in people in close contact with patients The virus is excreted by infected individuals in the stools for various periods up to months, but also from the upper respiratory tract for short periods during the early acute febrile days of the disease Discussion as to which is the most important route for the spread of the virus in epidemic periods will be found in other sections of this chapter.

The epidemics occur in the late summer and early fall. No adequate explanation of this seasonal incidence has yet been accepted In the northern part of the United States the peak of the epidemic is in September,

in the United States, Sweden and Australia, though smaller epidemics are now being reported from nearly every country, those in the tropical world being less definite and severe In spite of the relative rarity of the paralytic disease, we must consider that the virus is highly communicable, being spread from one human being to another in a fairly direct fashion It is clear that man is the only host in which a sufficient number of individuals naturally support enough virus propagation to maintain the agent

History of Epidemiology

Early accounts of paralytic poliomyelitis describe it as a disease of young children, as the name "infantile paralysis" so clearly suggests, and sometimes it was also spoken of as "teething paralysis" Only 25 years ago it was stated by a few dogmatic clinicians that the safest place to be in a polio epidemic was in bed with another patient The belief that the disease was not contagious resulted from superficial observations at a time when the disease was not recognized except with

indicated the opposite and he himself suspected what we now know as the truth, that many people get infected without evident illness This concept had been clearly stated by Wickman and was frequently emphasized by the leading epidemiologists of the present generation: Frost, Aycock and Maxcy. But it was difficult for most people to grasp the idea that poliomyelitic infection

3. An emotional dependence on the respiratory equipment which may be very great indeed.

Various devices for respiratory aid exist in addition to the tank respirator, though all are less efficient than the "iron lung." The chest respirator is a cuirass type of device that fits only over the front of the abdomen and the chest but is operated on the same physical principles as the tank respirator It is light weight, the arms and the legs are free, and it can be used in a wheel chair with a battery-powered motor. The Rocking Bed makes use of the principle that with rhythmical rocking of a recumbent patient, the abdominal contents push first the diaphragm up in head-down position and then down in head-up position and produces a tidal exchange of air which, although not adequate for complete respiratory exchange, supplements the patient's own efforts

Another nonmechanical device was discovered almost by accident Certain patients learned "glossopharyngeal" respiration to carry out what has been called "frog breathing." This is a procedure in which by rhythmic swallowing motions the patient is able, with his pharyngeal muscles, to push air down into his lungs and inflate them to a marked degree. This is the actual mechanism of breathing of frogs Recognition of this procedure in certain patients who had discovered it spontaneously was reported by Dail et al (1955) and Collier et al (1956) The procedure was analyzed, and then it was found possible to teach it to many other patients These patients can inflate their lungs to a very satisfactory degree and under great pressure, in fact, sometimes the pressure is so great that it is possible to inhibit the return of blood to the right side of the heart, and fainting can result The "rate" of such glossopharyngeal respiration is slow, and the resultant gas exchange is not adequate for acute or severe paralysis, and of course it cannot permit sleep. Nevertheless, this procedure is entirely practical and has enabled many people to go many hours without mechanical assistance and during that time to be freed for training and for the actual accomplishment of self-care and income-producing activity.

The various rehabilitation technics for assistive apparatus in the use of the arms and the legs is in a stage of very active progress in this country and already has produced some most satisfactory results. The activities of the respirator centers probably furnish one of the most dramatic examples of what can be done by imaginative and devoted work in total patient care for handicapped individuals. Although such care is very expensive indeed, its total cost may well be considered returned from the saving of money for the costly hospitalization of these patients who otherwise would live indefinitely in hospitals in tank respirators

EPIDEMIOLOGY

A review of the development of knowledge of the epidemiology of poliomyelitis makes a fascinating study and, if complete, would include most of the scientific observations made of this disease until recent years. With the first understanding of the disease only paralytic cases could be recognized, and thus studies of epidemiology were limited. By some, infantile paralysis was not considered a contagious disease, although shrewd suspicions of others many years ago suggested that the paralytic cases could not represent the whole story and that the disease was indeed contagious It is convenient to divide the history of the studies of this disease into different periods, depending upon availability of technics for study In the first period only the "shoe-leather" technic was available; no laboratory procedures existed, and observations were limited to studying epidemiology as it appeared, with apparent paralytic disease the only indication of the action of the infectious agent. With only careful observation of nature, valuable studies were carried out by many very effective workers One of the earliest and greatest of the epidemiologists working with these handicaps was Wickman, to whom we shall refer again.

The next step, a crucially important one, was the determination by Landsteiner and Popper that this disease was indeed due to a virus, and that the rhesus monkey was a laboratory animal which could be used to detect the virus. Many years passed with patient but plodding progress under the handicap of restriction to the rhesus monkey as the only experimental host.

Another great advance occurred when Armstrong (1939) demonstrated that cotton rats

not produce immunity against one another. Although the blood serum of convalescents was known on occasion to contain antibody capable of neutralizing virus, this was not invariably true, a circumstance which led to much confusion

It fell to Burnet and MacNamara (1931) to observe that there were 2 types of convalescent sera, each of which neutralized different samples (strains) of virus, but the full meaning of this escaped them. Paul and Trask (1933) had produced more than one paralytic attack in one monkey, as had Howe and Bodian (1941a, 1942), but they also were groping in the dark.

The answer to the riddle came almost accidentally from the practice of using the Lansing strain for both vaccination and subsequent intracerebral challenge It soon became apparent that animals vaccinated with the Lansing strain and able to resist several hundred thousand ID_{50} nevertheless easily succumbed to much smaller challenges of the strain called "Brunhilde" The animals also failed to resist a strain obtained in California from a fatal case named Leon Furthermore, Lansing did not protect against Leon, and so on around the circle (Bodian et al, 1949, Kessel and Pait, 1949) So by this route came recognition of the 3 virus immunogenic types; Brunhilde (I), Lansing (II) and Leon (III). Extensive investigation of more than 100 other virus strains failed to reveal one which did not fit into one of the above categories (The Committee on Typing of the National Foundation for Infantile Paralysis, 1951)

A great discovery was made in the early 1940's when money from the March of Dimes made monkeys more readily available Polio virus was isolated from individual stools and from urban sewage (Paul and Trask, 1941) It was also recovered from filth and occasional house flies trapped in areas of ready access to exposed human feces (Trask et al, 1943, Trask and Paul, 1943) The demonstration of virus in the sewage of Toronto, Canada, and Johannesburg, S. A, during months when there were no reports of paralytic poliomyelitis furnished inescapable evidence of an immense reservoir of subclinical infection (Mundel et al, 1946; Rhodes et al, 1950)

Another outstanding step in the study of poliomyelitis was the use of the chimpanzee as the laboratory primate closest to man This animal has a broad susceptibility to polio viruses and, most important, is highly susceptible to poliomyelitis infection by the route presumably normal in humans, that is, by oral feeding (Howe and Bodian, 1941b; 1944; Howe et al, 1950). It was possible in these animals to measure the rise of virus titer in the infected alimentary tract and the corresponding serum antibody response. It was found that serum antibody titers of 1 to 300 or greater prevented *alimentary* infection entirely in the chimpanzee (Howe, 1955, 1957), but that lower levels allowed it to take place, thus converting the animal into a convalescent, but probably permanently immune to paralysis (Bodian, 1953) Paralysis was inhibited at much lower antibody levels and was not observed in any animal exhibiting definitely demonstrable antibodies (Bodian, 1952).

Change in Age Incidence

For the last 30 years, exposure to poliomyelitis virus has clearly become more difficult in early infancy, resulting in a relative shift in the paralytic disease to a progressively older age group (Dauer, 1955).

The early relative immunity of adults was always subject to discussion. It was thought that perhaps adults were simply enjoying one of their traditional prerogatives, that by simple physical maturity they became more refractory to paralysis. One answer lay in the [illegible]

disease in question was poliomyelitis. Often it seemed more likely that vitamin deficiencies, or some other condition was involved Finally, Type I poliovirus was identified from several fatal cases in a midwinter outbreak of a paralytic disease in an isolated group of Arctic Eskimos (Peart, 1949) These unfortunate people suffered attack rates of 20 to 25 per cent at all ages up to 60 years, thus indicating that their previous freedom from paralysis, for adults as well as children, was lack of exposure to the virus and that maturity per se played no part

During World War II, increased exposure was reflected by a 10-fold increase of paralytic rates among American troops stationed in Southeast Asia or the Eastern Mediterranean theaters as compared with those associated with duty in this country or continental Europe (Paul, 1949)

The habit of the disease, as time went on, to attack an older age group and to be epi-

was an unrecognized episode of childhood, as frequent as the flamboyant nuisance of measles, and resulting in lifelong freedom from the threat of paralysis.

Wickman was entirely ignorant of the etiologic agent and possessed no method of study except the observation of the human and clearly apparent disease, but he recognized it to be an infection communicated from one person to another He apparently was fortunate in being able to observe the action of a virulent virus strain which produced a high percentage of paralytic cases in small Swedish villages Such a situation enabled him to analyze the movements of people with enough accuracy to rule out common media such as food, milk, or water and to trace numerous chains of contact through paralytic cases Nonetheless, he recognized that there must also be many asymptomatic infections, although he could not estimate their relative frequency

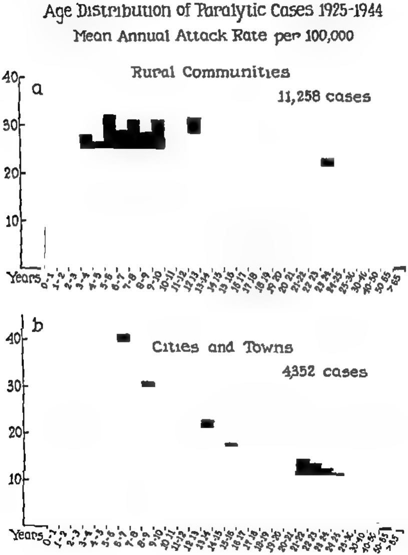
The first step that made it possible to use an animal host of the disease to study its nature began nearly 50 years ago with Landsteiner and Popper's success in causing a characteristic paralytic disease in the rhesus monkey At that time it was convincingly shown by the crude and expensive experiments made necessary by the limitation of the use of the rhesus monkey that neutralizing antibodies against the virus persisted for many years in convalescents from paralytic disease and were found also in those who had survived epidemics without suffering any apparent infection. Antibodies were believed to have intimate relationship to the lifelong immunity which seemed to follow paralysis, but cost prohibited the use of adequate numbers of animals for crucial studies to prove it Progress in knowledge was further handicapped by the fact that all strains of the virus were considered to be similar antigenically, and in fact only the Lansing strain (Type II) was in general experimental use in rhesus monkeys. With no knowledge that there were different antigenic types of polio virus, and since monkeys could sometimes be infected in whom antibodies had been demonstrated, it is not surprising that there was no agreement, even up until the beginning of the 1940's, as to the role of the circulating antibody in the prevention of paralysis Opinions ranged through every possible shade from no connection at all between antibodies and resistance to human disease to an all-important relationship.

The use of the rhesus monkey as an experimental animal was indeed a great advance However, the rhesus monkey did not provide a very good model for man, since this animal could be regularly infected with poliomyelitis only by direct contact between the virus and some exposed part of the nervous system. Nevertheless, much was learned Morgan and others (1947) found that if rhesus monkeys were vaccinated by large intramuscular injections, either with living or formalin-inactivated Lansing virus (Morgan, 1948), immunity to paralysis, from subsequent challenge, resulted with notable regularity. They were able to show that the serum antibody level rose in proportion to the amount of vaccine given and eventually attained titers of 1 to 1,000 or greater If the monkey possessed an antibody level of this magnitude at the time of intracerebral challenge, it always escaped paralysis, even though several hundred thousand doses of the same virus were injected directly into the brain (Morgan, 1949) Such a test was recognized to be far more drastic than any condition naturally occurring, but it clearly showed that the most susceptible tissue of the body could be protected from direct contact with virus if enough circulating antibodies were present.

For almost 30 years, in spite of devoted work, progress was greatly limited to the restrictions inherent in the fact that the rhesus monkey was the only experimental animal In 1939 Armstrong made another discovery of crucial importance He showed that he could cause paralytic disease in cotton rats and mice with injection of virus from monkey or man Again the handicap existed that the virus needed to be injected directly into the cerebrum. However, this success provided a new impetus to investigation by making available an inexpensive means for titrating antibodies and measuring virus with some accuracy This technic was used with profit in studying the propagation of the virus in these animals and the subsequent rise of antibodies The neutralization test carried out with the Lansing strain (Type II) against sera of unknown antiviral potency opened the way to an understanding of the minimal level of antibodies required to suppress virus growth by the combined use of the rhesus monkey and cotton rats and mice

It gradually became apparent that there were subgroups of poliomyelitis virus which were antigenically distinct and under artificial conditions in the laboratory, at least, did

Poliomyelitis is a disease which travels with the crowd, and frequently it has been shown that the acquisition of antibody or the incidence of paralytic disease is conditioned by the numbers and the propinquity of people living in a given area. The larger and more crowded the population, the younger the age at which either paralytic disease becomes manifest or antibody is acquired. Figure 58, taken from Olin (1952), contrasts the age incidence of carefully verified paralytic poliomyelitis cases in urban and rural areas of Sweden. This picture is repeated in any country where poliomyelitis is epidemic,



Lippincott)

demic has taken place in all the countries where poliomyelitis first ceased to be sporadic and demonstrates the consistence of the same initial forces which produced epidemics. It seems perhaps unfair at first to attribute this all to modern plumbing when nearly every phase of life is changed, but it was evident that the transfer of virus from pharynx to pharynx is less efficient in causing natural immunity than the ingestion of material contaminated by infected feces.

With better methods and less expensive ones being available for studying the distribution of virus and the presence of antibodies, epidemiologic studies of the disease became very significant when carried out elsewhere than in the modern countries where paralytic and epidemic poliomyelitis was common. One of the most revealing studies was that carried out in Cairo, Egypt, reported by Paul and his associates in 1952. They showed that most infants in Cairo, by the time they had reached the age of 2 years, had already acquired a significant level of antibodies to all 3 types, while in a city in a similar latitude and size in the United States only a very small percentage of children at this age had developed antibodies. It was noted that actual paralytic poliomyelitis probably occurred in Cairo much more often than had been reported or recognized, but it was evident that it was almost wholly "infantile" paralysis. The study was carried out with the use of mice for the detection and the measuring of virus and antibodies against the Lansing strain, Type II, but with the use of monkeys for the other types. The incidence of antibodies dropped off sharply in the early months of life but increased again sharply, so that roughly 80 per cent of the infants, in regard to some types, were immune or at least had antibodies at the age of 2 years.

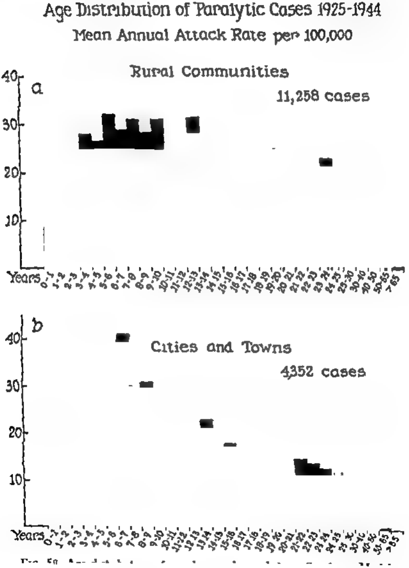
It became clear there that the virus was widespread in sewage and stools of many individuals not ill with the disease, and that natural infection in Egypt and other countries with similar poor sanitation, took place by the oral route without producing much disease, hardly any after infancy, but caused the development of permanent immunity in almost all young children.

The question arises as to why, if infection was widespread, the infants did not show a high incidence of paralytic disease in the process of developing immunity. Paralytic disease, true infantile paralysis, does occur in Egypt, but why is it not common? Data as to actual incidence are admittedly poor, but it seems certainly not great. There are two plausible explanations. Central nervous system disease from poliomyelitis seems to carry with it less risk of extensive paralysis in the young child than in the adult. This is evident in our own country where the severity of paralysis in adults who have central nervous system disease seems to be greater than that in children, if not infants. Another explanation seems to be highly probable. The natural immunity of the mother can be transferred to the infant through the placenta, as in the case of measles, and the newborn baby thus has passive antibodies which protect him for a number of months. It is probable that this passive immunity in the children of countries with poor sanitation protects the infant from paralytic disease while the infant is acquiring active immunity by the ingestion of potent viruses. It seems clear that in our country the price we pay for better sanitation, with its greatly reduced infant mortality from other conditions, is the failure of development of a natural immunity to poliomyelitis. Thus we have a logical explanation for the increased incidence of poliomyelitis in countries with better sanitation. This also explains the change in age incidence with the increasing involvement of older people that has been apparent in the last decade in this and European countries.

Spread of Virus. The presence of virus in the blood, the pharyngeal mucosa and its secretions, occasionally in saliva and the anterior part of the mouth, and lastly in the feces offers many possibilities for egress into the environment. It is now generally agreed that man is the only species in which the virus propagates; hence, he must be consid- [illegible] of virus

son-to-person transfer takes place without the intervention of any vector, even a blood-sucking arthropod. This latter possibility can be ruled out by a comparison of concurrent epidemics of western equine encephalomyelitis and poliomyelitis in Minnesota (Eklund, 1946). An epidemic of equine encephalomyelitis reached its peak in the month of July and then rapidly receded during August, which marks the beginning of colder weather in this state, and the disappearance of mosquitoes. At the same time an epidemic of poliomyelitis was just beginning and reached its maximum during the months of August and September but did not entirely subside until sometime in January.

Poliomyelitis is a disease which travels with the crowd, and frequently it has been shown that the acquisition of antibody or the incidence of paralytic disease is conditioned by the numbers and the propinquity of people living in a given area. The larger and more crowded the population, the younger the age at which either paralytic disease becomes manifest or antibody is acquired. Figure 58, taken from Olin (1952), contrasts the age incidence of carefully verified paralytic poliomyelitis cases in urban and rural areas of Sweden. This picture is repeated in any country where poliomyelitis is epidemic,



Lippincott)

although the differences between rural and urban areas grow less striking each year The presence of virus in the pharynx (Howe et al, 1945, Sabin, 1955) and the mouth, as well as in the feces (Trask et al, 1940), gives rise to a dilemma regarding the more important route by which it is transmitted from one person to another Every person infected with this virus for the first time, whether paralytic or asymptomatic, probably carries it in his throat for a period of 10 days or 2 weeks Some very young individuals also have virus in their mouths (Sabin, 1955, Howe, 1958), although the frequency and the duration of this occurrence is not yet determined Probably everyone experiencing a first infection sheds fecal virus for a week or more, but it persists in many during the 2nd to the 4th weeks (Horstmann et al, 1946, Schabel et al, 1950) and has been recorded as long as 84 to 123 days after the onset of infection (Goffe and Parfit, 1955, Lepine et al, 1939)

From an epidemiologic point of view there is reason to think that in the countries of the north and the south, so-called temperate zones, where poliomyelitis is epidemic, the fecal route may not be the all-important one, although it probably is in countries with more primitive types of sanitation

It is strikingly evident that the incidence of paralytic disease does not follow the pattern of enteric infections such as typhoid. The spread of the disease has seldom followed milk routes or water ways nor apparently often followed the "fingers, flies, feces" sequence of infection In the epidemic areas, evidence has been conspicuously lacking for dissemination of virus by any sort of common medium such as food or drink Water has never been incriminated (Maxcy, 1944), but a few milk-borne epidemics have been recorded These were traced to unpasteurized milk contaminated by an infected milker (Aycock, 1927, Dingman, 1916) Furthermore, secondary cases have not arisen from contact with known infected individuals during the long late stages of their disease, although many doubtless continue to eliminate fecal virus. On the contrary, there is striking agreement regarding the infectious period, as determined independently by 3 groups of [illegible] observing the incubation periods [illegible] case (Casey, [illegible] 1943; Silverthorne et al, 1949). The primary case appears to be most infectious from 7 to 10 days before and after the onset of symptoms. This corresponds very closely to the time during which virus may be demonstrated in the throat, although its duration is doubtless shorter in the mouth It was disappointing to learn that most family infections are nearly simultaneous rather than sequential with incubation periods of 7 to 14 days This was why gamma globulin given to contacts of the first patient in a family seldom has time to prevent other infections in that family.

One would naturally expect infection to reach its highest incidence in very young children, who are the most susceptible segment of the population. Extensive studies, now made possible in family groups by the use of tissue cultures, show beyond doubt that children under 5 years of age are probably the principal reservoirs of virus and the ones who introduce infection into the household. Anyone who has associated with children at this so-called "dirty age" can easily credit person-to-person transfer of virus from either end of the alimentary tract The study of Bodian and Paffenbarger (1954) also clearly indicates that a large proportion of so-called "index cases" in young adults probably were infected by their young children. On the contrary, Wehrle (1956) found no evidence of antibody rise in 50 hospital personnel (many without antibody of any type) during several weeks of exposure on acute poliomyelitis wards.

The Relationship of Artificial Immunization to the Spread of Virus

Discussion of the prevention of poliomyelitis by vaccine is given in Chapter 24 The influence of this mass immunization procedure on epidemiology is obviously of importance, and we must discuss briefly the relationship of artificial immunization to the spread of the virus.

The possibility that vaccination may reduce the duration of alimentary infection and limit its titer has important implications relative to the amount of virus in a community and to the passage of virus from one individual to another. If less virus were shed into the environment following vaccination it should be possible to immunize enough people to break the chain of transmission in certain areas where the virus of poliomyelitis would share the same fate as that of smallpox. However, it is very difficult to quantitate poliomyelitic infection without disease

in human beings, since many specimens are needed simply to measure its duration For

On the other hand, in chimpanzees it is possible to produce alimentary infection by the feeding of virus (Type I), after which one may obtain throat and mouth swabs, feces and blood daily for as long a period as desired Thus it is possible to observe the

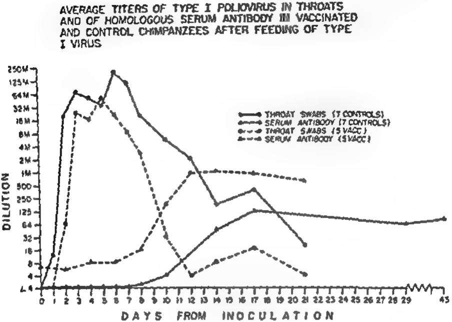


FIG 59A (Howe, H A, 1957, Day-by-day response of vaccinated chimpanzees to poliomyelitic infection, Am J Pub Health *47*, 871-875)

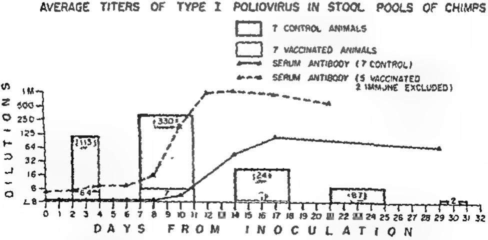

FIG 59B (Howe, H A, 1957, Day-by-day response of vaccinated chimpanzees to poliomyelitic infection, Am. J Pub Health *47*, 871-875)

duration and the amplitude of poliomyelitic infection at the above sites in relation to the rising titer of homologous serum neutralizing antibody (Howe, 1957). This is shown in Figure 59A for virus in the throat and in Figure 59B for virus in weekly stool pools. The titers represent an average of 5 vaccinated and 7 control (unvaccinated) animals. These Figures clearly show a consistent lowering of alimentary Type I titers, as well as a shortening of the carrier state in the vaccinated animals, as compared with the controls. Despite the intentionally low level of serum antibody in the vaccinated animals, they responded more rapidly and developed higher titers than the controls, but 2 vaccinated animals with high serum antibody titers at challenge are omitted, since they did not become infected. Virus titer declined as antibody rose with the 2 lines crossing at about the same point of equilibrium (1 to 64) in both groups of animals.

In a roughly comparable series of specimens that had been recently collected, on single occasions from paralytic patients and their family contacts, it is equally evident that virus titers in the throat, the mouth and even the stools bore an inverse relationship to the titers of homologous (Type I) serum antibody. However, stool virus was being excreted (at relatively low titer) in the presence of serum antibody levels above any observed to be compatible with the presence of virus in the throat or the mouth. While these observations are still fragmentary, they follow the same pattern as that observed in the chimpanzee except for the fact that in man the fecal virus titers are lower than the pharyngeal, just the reverse of the chimpanzee. For this reason it is doubtful whether the antibody levels achieved by vaccination would appreciably effect the elimination of fecal virus, a finding essentially in agreement with that of Fox (1957). Thus the epidemiologic pattern of poliomyelitis might show little change if the fecal route is of primary importance in virus dissemination. On the other hand, transmission of virus by the oropharyngeal route might be affected profoundly (Bell, 1948).

Actual observations of the effect of vaccination on the spread of virus are not yet clear. In the field study of the effect of vaccine, it was not apparent that nonparalytic

study. Moreover, it seems probable so far that the total reduction of poliomyelitis in 1956 and 1957 was greater than could be explained by the number of vaccinated individuals.

cial factor that makes the difference between infection and disease. What determines the "sorties" of the virus from its seat of innocent growth in the mucosa of the gastro-intestinal tract to the blood stream and the lymphatic channels, and, more specifically, what is the crucial factor that allows the virus to reach the central nervous system where its action causes the paralysis that makes the disease important?

We still are ignorant of one of the most striking characteristics of epidemics of poliomyelitis, that is, the seasonal incidence, which is in the summer and the early autumn in temperate zones. There has always been a suspicion that this could be related to an insect vector, but there is no support for this intriguing and at first thought logical hypothesis.

CONTROL

It seems clear that the virus of poliomyelitis is spread through the stools of infected individuals for considerable periods, and for short periods during the acute stages of the disease it is spread through the upper respiratory secretions. Attempts at quarantine have been undertaken for many years, and any outbreak of poliomyelitis presents a great problem to local health officers. One can emphatically challenge the success of any procedure used up to the present to control the spread of the disease. In the past, however, before knowledge of the spread of the virus was prevalent, isolation technics were more or less ignored in many places, though we had no evidence that the spread of disease was thereby greater. In large cities, patients with poliomyelitis are sent to isolation hospitals, but in many other areas they have been accepted for years in general hospitals without any specific or at least adequate isolation technics and with very little evidence of cross-infection. However, although there is little evidence of cross-infection of the disease within the hospital from patient to pa-

tient, there has been a considerable number of instances of transmission of the disease from patient to attendant, nurse or physician. From what has already been said about the virus in relationship to infection versus clinical disease, it becomes apparent why isolation technics might be ignored without evidence of any increased risk of the disease. The virus is widespread, therefore, isolation of a patient with clinical evidence of the disease succeeds at its best only in the prevention of the spread of a very tiny fraction of the virus excreted by the total number of infected individuals.

It seems certain that isolation technics have had little influence in controlling the spread of the disease, and that it is probably impractical ever to hope that the disease can be so controlled

The peak of incidence of the disease is in the late summer and fall There has been little evidence that closing swimming pools, delaying opening of schools, or any other public health procedures have actually influenced the incidence curve of the epidemic It is not apparent that a reduction in incidence in any epidemic occurring abruptly after some public health procedure has been instituted has actually occurred because of it. This, of course, cannot be used as an argument for abandonment of all attempts at isolation, and each community faced with an epidemic must of necessity institute what reasonable and practical steps are available

There is a great deal of question whether summer camps where poliomyelitis has occurred should be broken up and exposed children sent back to their homes where they may possibly further spread the virus However, pressure by parents usually demands this Justification for delaying the opening of a school is greatest where the starting of school would mean bringing back into a community a great many children who have been away all summer and thus scattered in various communities The closing of swimming pools is from one point of view a cheap procedure to carry out It causes only some disappointment, and it is difficult, in the face of an epidemic, for any public health organization to urge the continual use of public swimming pools where spread of enteric infection most logically could be aggravated

Many virus surveys show that the infection of one child in a family results in spread of the virus to practically all who are susceptible (Nolan et al, 1955; Wenner and Tanner, 1948, Gelfand et al, 1957; Howe, 1958). The evidence on this point is overwhelming, but the modest study by Goffe and Parfitt (1955) probably will deliver the *coup de grace* to the old notions of quarantine. In a small but modern English village (A) comprising 7,400 inhabitants, 2 cases of paralytic poliomyelitis occurred between January 8 and 13, 1954. There were also 3 cases among 96 persons residing in a nearby hamlet (B) which had no public water supply or sewage system The city fathers of "A" acted promptly, and on January 14 quarantined their cases Seven days later 8 out of 17 healthy household contacts were shown to have alimentary infections, and virus was found in sewage collected from a section of "A" quite remote from that of the "cases" Although the quarantine was still being maintained rigidly during the remainder of January, February and March, on March 2 a positive stool was found in 1 of 18 school children of "B"; and a collection of sewage from "A" on March 16 to 18 showed the presence of virus, even though there had been no recognized cases in this section at any time during the outbreak One stubborn contact continued to have positive stools for at least another month (beyond the 84th day)

Control by means of vaccines is discussed in detail in Chapter 24

Poliomyelitis: Pathogenesis and Histopathology

INTRODUCTION

The nature of a viral infection is determined by both stable and variable properties of the viral and host cell reacting system. In very few viral infections are the host variables so numerous and so complex as in poliomyelitis. This disease is an occasional neuropathologic resultant of a sequence of relatively silent physiologic events of infection which occur in most members of the human species at least once in their lifetimes. Understanding of the silent as well as the overt events of infection has increased greatly in recent years, although several basic problems are still unresolved. Nevertheless, present knowledge of the pathogenesis of this disease makes possible considerable insight into the factors which determine the outcome of infection, as well as those which are the basis of diagnosis, treatment, or prevention. The intimate details of the interplay of these factors can be approached best after consideration of the sequence of events in natural infections.

PORTAL OF ENTRY AND EXIT OF VIRUS

Epidemiologic evidence has led to the inescapable conclusion that the virus of poliomyelitis is spread directly or indirectly from person to person. No intermediate host is known. The crucial role of a human reservoir of infection is supported by the finding of virus in oropharyngeal secretions and in feces well before onset of symptoms or of other signs of infection. Although the precise details of the manner of spread of infection from person to person are not known, it is now generally believed that entry of virus is by way of the upper alimentary tract, and exit by way of the upper and the lower alimentary portals. The previously held belief that virus enters by the nasal route has been abandoned.

PRIMARY VIRAL IMPLANTATION AND PRIMARY SITES OF VIRAL MULTIPLICATION

The early stages of infection in poliomyelitis were largely unknown or misunderstood before experimental work with freshly isolated strains began on an experimental model, the chimpanzee, which is the anthropoid ape most closely related phylogenetically to the human species. The responses of the chimpanzee after virus feeding are indistinguishable from those of human beings with respect to observable events of infection (Bodian, 1952, 1955), and recently the similarity of the infection has been confirmed by studies of the course of infection in human beings

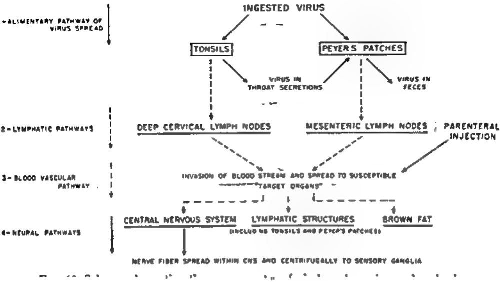
SITES OF POLIOMYELITIS VIRAL MULTIPLICATION AND PATHWAYS OF VIRAL SPREAD
SHOWN SEQUENTIALLY IN CHIMPANZEES AFTER VIRUS FEEDING
(OR PARENTERAL INJECTION)



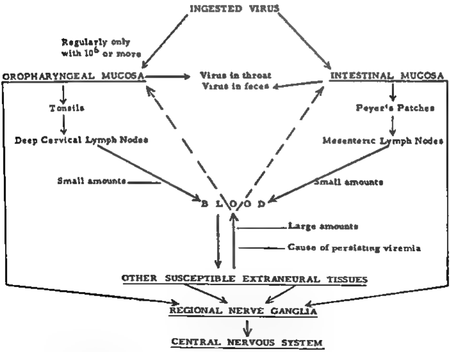


FIG 61 Schema of possible pathogenesis of poliomyelitis based on a synthesis of data available in 1956. (According to Sabin, 1956)

after feeding of avirulent strains (Sabin, 1956) Therefore, gaps in our information concerning the distribution of virus in human tissues during the earliest stages of infection can be filled tentatively by experimental data from chimpanzees sacrificed early after the feeding of virulent strains

The appearance of rising concentrations of virus has first been observed in throat secretions and in feces within 1 to 3 days after virus feeding and approximately 1 to 2 weeks prior to onset of paralysis in chimpanzees fed virulent strains The early appearance of virus in throat and feces after virus feeding thus corresponds to virus isolation at a similar interval prior to onset of symptoms in the natural infection (Gordon et al, 1947, Schabel et al., 1950) The earliest analysis of viral distribution in tissues in the presymptomatic period in chimpanzees has revealed the presence of virus only in tonsillopharyngeal tissue and in the Peyer's patches of the ileum as well as in draining lymph nodes in the deep cervical region and in the mesentery, respectively (Bodian, 1956)

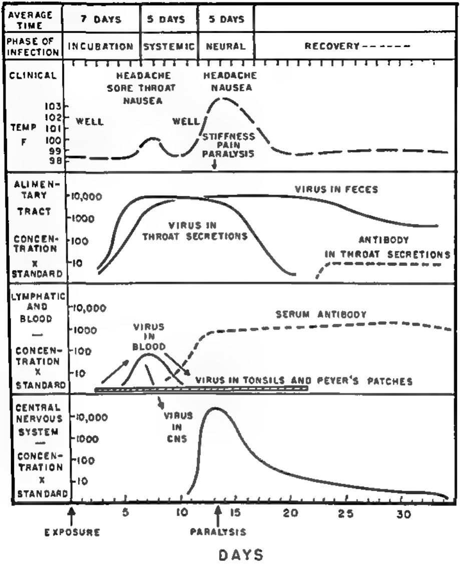
This distribution indicates that primary viral implantation and multiplication occur in one or both of two distant sites in the alimentary tract, namely, the mucosa of the throat and of the ileum Although the surface epithelia in these two sites are quite different in type, both are characterized by the presence of large aggregations of lymphatic follicles in the lamina propria of the mucosa itself. In human necropsy material, virus has been isolated with relative ease only in those tissues most frequently found infected in chimpanzees, namely, central nervous system, tonsillopharyngeal tissue, wall of the ileum, and lymph nodes (Sabin and Ward, 1941; Wenner and Rabe, 1951)

There are several points of great theoretical and practical interest in relation to the primary infection of the alimentary tract. First of all, it is probable that most infected persons, especially those exposed to avirulent strains in nature, experience only the infection in the alimentary tract and regional lymph nodes, without further spread of virus in the body. Nevertheless, such individuals may exhibit a serum antibody response and become subsequently immune to the infecting type of virus Since such individuals constitute the great majority of infected persons, they also constitute the greatest reservoir of infection for other individuals by means of the virus excreted from the alimentary tract Some of the individuals who experience no apparent viral invasion of the central nervous system, as well as many who do, suffer the symptoms of the so-called "minor illness," such as fever, sore throat and intestinal upsets. These symptoms may correspond to the primary infective process in the alimentary tract, although specific histopathologic lesions have not been clearly correlated with the presumed sites of alimentary viral multiplication Although hypertrophy of Peyer's patches has been described in autopsied cases, these structures have not as yet been assessed separately for viral content in human material

Since the sites of viral multiplication in the alimentary tract are the obvious sources of virus which is excreted by the infected asymptomatic carrier, abortive case, or paralytic patient, it is of interest that the upper and the lower alimentary tract differ with respect to time of persistence of viral excretion. Virus recovery from tonsillopharyngeal swabs has been reported only infrequently after the first week following onset of the major illness, whereas virus recovery from feces is readily accomplished during the first 3 weeks after onset Recovery from feces is often possible for several weeks or even for months after onset

LYMPHATIC AND HEMATOGENOUS VIRAL DISSEMINATION

There is no doubt at the present time that shortly after the primary stage of infection in the wall of the alimentary tract, virus is shed inwardly into lymphatic and blood vascular channels as well as outwardly into the alimentary lumen The exact mechanism of the humoral shedding is unknown, but it results in the spread of virus to regional lymph nodes, to the presence of appreciable amounts of virus in the blood serum early in the period before onset of the major illness (Horstmann et al, 1954, Bodian and Paffenbarger, 1954), and to the finding of virus in systemic lymph nodes, such as axillary and inguinal



infect 50 per cent of test units (monkeys, mice, or tissue cultures). The "standard"

nodes, in autopsied cases (Wenner and Rabe, 1951)

Whereas the invasion of regional lymph nodes from the alimentary mucosa has little or no clinical importance and may lead only to reinforcement of the immune response which probably initially occurs in the lymphoid tissue of the mucosa, the invasion of the blood stream by virus is fraught with more ominous possibilities The source of the virus which enters the blood stream is unknown, although it is suspected that virus from the lymph nodes may contribute to the viremia After initial stages of viremia in chimpanzees, the dissemination of virus to systemic lymph nodes and the brown fat of suprasternal, upper axillary, and paravertebral regions may lead to secondary sites of viral multiplication, particularly in the brown fat In this tissue virus has been found in extremely high concentration in experimental primates (Shwartzman et al , 1955, Bodian, 1956), and this leads to the possibility that reinforcement of later stages of viremia may occur from virus shed from the brown fat

The occurrence of a stage of viremia analagous to that which occurs in other viral infections in the presymptomatic period also raises the question of whether invasion of the central nervous system occurs by way of the blood stream, just as invasion of the target organs of the arthropod-borne viruses and viruses of the exanthems and of hepatitis occurs by way of this route Although the occurrence of viremic invasion of the central nervous system in the human infection is held by some to be of importance, controversy on this issue still continues, and no final answer can yet be given Evidence for the opposing points of view is presented in detail elsewhere (Bodian, 1955 and 1956, Sabin, 1956) The importance of a viremic stage of infection and of a viremic route of central nervous system invasion by virus is 2-fold First, such a mechanism of invasion would enhance the importance of serum antibody in preventing infection of the central nervous system Second, such a mechanism has to be assessed carefully in relation to the occurrence of nonimmuno- [illegible]

rier." These factors will be considered below.

DISSEMINATION OF VIRUS ALONG NERVE FIBER PATHWAYS

Experimental work has left no doubt that poliovirus is capable of spreading along nerve fibers in both the peripheral as well as in the central nervous system (CNS). The exact mechanism of this spread is unknown. In natural infections the characteristic and restricted distribution of lesions in the CNS is so similar to that which has been shown in experimental animals to be determined by nerve fiber spread that one must assume that it also is determined by nerve fiber spread of the virus along restricted pathways in the CNS However, evidence for spread of virus along nerve fibers from the alimentary tract to the central nervous system is not available, although nerve fiber spread to the CNS following intranasal, intramuscular and intrasciatic inoculation can be demonstrated under experimental conditions in monkeys.

Figures 60 and 61 summarize two points of view concerning the present status of the modes of spread and the sites of viral multiplication in poliovirus infections

INFECTION OF THE CENTRAL NERVOUS SYSTEM

Following the relatively silent events of infection in the primary sites of multiplication in the alimentary tract, and possible intermediate sites in lymph nodes, or brown fat, an occasional infected individual experiences the effects of viral multiplication in the major secondary site, namely, the central nervous system The pathologic effects of this complex process will be considered below The time course of viral increase in nervous tissue such as the spinal cord, and of its recession, is probably similar to that in other tissues infected with certain other viral agents This time course, which is summarized in relation to other events of infection in Figure 62, is characterized by a sharp rise in viral concentration during the day prior to onset of the major illness In experimental animals where this process can be studied quantitatively, it is clear that high concentrations of virus are maintained for 1 or 2 days, following which a less precipitous but yet rapid decline of virus takes place Within 1 or 2 days the de-

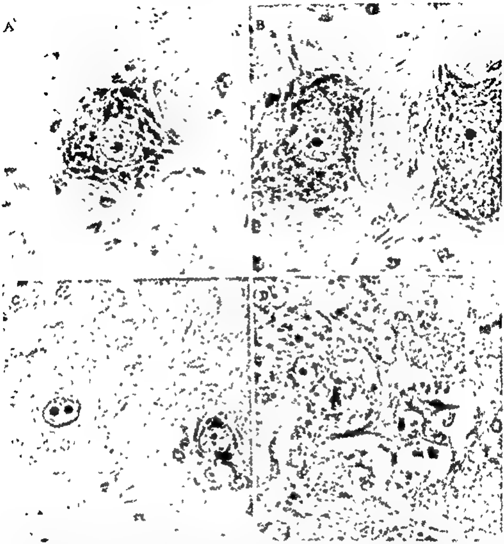


FIG 63 Regressive stages in spinal cord motoneurons in poliomyelitis early acute stage Hematoxylin-eosin-azure stain Rhesus spinal cord ×600 (A) Normal anterior *horn cell Note massive Nissl bodies in cytoplasm, central position of nucleus, large* basophilic nucleolus and dispersed chromatin (B) Early change due to virus activity Note diffuse decrease in size of Nissl bodies (chromatolysis) and tendency for aggregation of oxychromatin in nucleus (C) Severe diffuse chromatolysis, with disappearance of Nissl bodies Cytoplasm shows faint diffuse basophilia Nucleus is shrunken and contains a large eosinophilic inclusion body, as well as an intact nucleolus The inclusion body is apparently formed by clumping of oxychromatin but does not occur in all injured cells Note absence of inflammatory cells in vicinity, or of "edema" (D) Irreversibly injured motoneuron, showing neuronophagia by polymorphonuclear leukocytes and macrophages All basophilia is usually lost at this stage of necrobiosis (Photographs in Figs 63-66, 68, 70-72 by Chester F. Reather)

cline of viral concentration reaches a level which is in the neighborhood of minimal detectable virus activity by present methods of analysis. However, virus may persist at this level in experimental animals for as long as 4 weeks after onset of paralytic illness. It is not known whether the sharp damping of viral infectivity in nervous tissue is due to a generalized immune response, local immune reaction, or inhibitory factors unrelated to serum or local antibody. The decline of viral concentration is the same in animals inoculated intracerebrally and in which no appreciable serum antibody response occurs, as it is in natural infections or in experimental alimentary infections in which a high serum antibody response has already become apparent before onset of paralytic disease. Figure 62 summarizes the present state of knowledge concerning the time relations and quantitative extent of pathogenic events in relation to the clinical course of paralytic disease.

PROVOCATIVE OR PREDISPOSING FACTORS IN CENTRAL NERVOUS SYSTEM INFECTION

Experimental work of the last decade has thoroughly established the fact that strains of poliovirus may not only differ with respect to antigenic type but, within each immunologic type, exhibit striking differences in virulence or invasiveness. These differences and the ability of viral strains to invade the central nervous system from the periphery or to produce severe pathologic effects after establishing infection within the central nervous system determine to some extent the outcome of infection. In addition to these viral factors there are certain physiologic variations of the host which also play a role in determining whether an infected individual will experience

after a primary infection are (1) peripheral trauma and (2) metabolic changes in the host induced by stressful conditions. With the latter should perhaps be grouped the increased susceptibility which appears to occur during pregnancy or with increasing age in both sexes. The mechanism of action of these predisposing host factors is not clearly understood. However, there is evidence which has associated the effects of trauma and peripheral injection, as well as both recent and long-standing tonsillectomy, with an increased penetrability of the so-called "blood-brain barrier" in the portion of the central nervous system associated with the traumatized peripheral area. The more general effects of pregnancy and increased age are sometimes attributed to modifications of corticosteroid activity. For example, experimental work has clearly shown that injections of cortisone increase the risk of paralysis in animals exposed to polioviruses. The predisposing effects of peripheral trauma are also of interest in that the risk of paralysis is not only increased but the localization of initial paralysis tends to occur in the extremity which has been traumatized. The preferential localization of paralysis to a limb injected with nonviral materials such as penicillin or diphtheria-pertussis-tetanus antigen has been clearly shown to occur in epidemics, but recent evidence has confirmed the earlier impressions that the total force of this effect in any epidemic is extremely small in terms of the total number of individuals involved in the epidemic.

The mechanism of the preferential localization of paralysis to an injected limb, or to bulbar centers following recent tonsillectomy, is a matter of dispute. One point of view is that the trauma serves to localize circulating virus in the injured nerve fibers, along which ascent to the CNS occurs. Another suggested possibility is that the trauma produces a reflex increase of penetrability to circulating virus of blood vessels in the motor centers corresponding to the injured peripheral muscle.

THE NATURE OF THE LESIONS IN POLIOMYELITIS

The nature of the central nervous system lesions in poliomyelitis, as distinct from their distribution in the central nervous system, and the clinical consequences of the lesions, are 2-fold in character. The earliest, and therefore the primary, lesions are changes which appear in nerve cells in the preparalytic period. Since these changes may occur in the absence of inflammatory exudate, and in

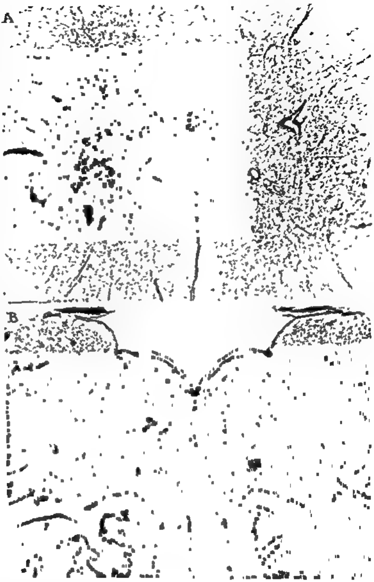

FIG. 64. Unusual human case of fatal spinal paralysis, with little brain-stem involvement H40, 17 days after onset of disease Gallocyanin stain (A) Section of lumbar cord showing complete motoneuron destruction and massive inflammatory reaction, especially on left side Note the heavy perivascular infiltrations, characteristic of the subacute and early convalescent periods (×20) (B) Same case as in A, showing the relatively slight involvement of the medulla oblongata (×10)

the margin of safety of each center before a clinical effect is observed The evidence from experimental work and from human material is overwhelmingly clear on this point Neuronal and inflammatory lesions may be found regularly in any susceptible center, including the anterior horn of the spinal cord, in persons who have never exhibited symptoms which are known to follow massive injury to such centers In experimental primates neuronal and inflammatory lesions may indeed be [illegible]

this is that severe lesions and concentrated damage to nerve cells are usually necessary *to produce* dysfunction at the clinical level, therefore, one must look for centers which are severely involved for the site of origin of clinical *signs*

experimental animals have been shown to be associated with the development of high concentrations of virus, the conclusion is inescapable that these nerve cell lesions are the *result of virus multiplication and not of the* inflammatory process which follows as a secondary response to nerve cell injury (Fig 63). Additional evidence for this view comes from the fact that in infections with some virus strains it can be shown that little inflammatory change occurs, and yet extensive nerve cell lesions and virus multiplication occur. The changes in nerve cells in the acute stage of poliomyelitis have been studied in early fatal cases in human beings and in monkeys and have been shown to be alike in the 2 species Since earlier stages and better tissue preservation can be obtained in the monkey, studies in this species have yielded more detailed information (Bodian, 1948, 1949)

Although the injury and the destruction of nerve cells may be independent of inflammatory changes, the latter do not occur in the *absence of susceptible nerve cells* For example, in regions of the thalamus deprived of nerve cells by means of retrograde degeneration following ablation of the cerebral cortex, the inflammatory changes of poliomyelitis do not occur even when virus is introduced directly into such areas This suggests that although the inflammatory reaction as it develops may be complexly determined, its origin, at least, is dependent upon a specific reaction of the virus with nerve cells

The changes in nerve cells may occur with extraordinary rapidity so that some motor nerve cells are destroyed in the preparalytic period The sequence of changes leading to destruction of cells found in the preparalytic and the early paralytic stages in rhesus monkeys is summarized in Figure 63 (A, B, C, D) A shows a normal anterior horn motoneuron B shows 2 infected motoneurons in an early stage of dissolution of cytoplasmic Nissl, bodies C shows a motoneuron with complete cytoplasmic chromatolysis, adjoining a small normal nerve cell. The chromatolysed motoneuron contains a spherical intranuclear acidophilic inclusion body, such as occurs in certain other neurotropic virus infections (Type B inclusion), but distinct from the Type A intranuclear inclusion bodies of infections with the herpes-B virus group of viruses D shows a necrotic neuron, with nucleus destroyed and cytoplasmic basophilia completely removed. Phagocytosis of this motoneuron is in progress (neuronophagia). *Many cells pass through most of these stages without evidence of surrounding inflammatory cells or exudate.* It is evident that when dissolution of the cytoplasmic Nissl substance is advanced, changes in the nucleus begin. When irreversible changes have occurred, the necrotic cell may be removed by neuronophagia due to leukocytes or macrophages or may undergo lysis

The changes in nerve cells in the acute stage are accompanied by an increase of inflammatory cells which soon may reach tremendous proportions (Fig 64A). Three principal types of such cells are found in the earliest stage: *polymorphonuclear leukocytes*, mononuclear leukocytes, and macrophages The polymorphonuclear cells may be extraordinarily numerous in some cases but persist only for a few days. The microglia are the active macrophages during the acute stage but persist in modified forms for weeks Mononuclear cells are predominantly lymphocytic cells and are present diffusely in the tissue for 2 or 3 weeks but persist as perivascular accumulations for many months.

In any attempt to analyze the relationship of lesions to clinical manifestations it is important but not necessarily easy to determine whether symptoms are the result of primary nerve cell injury or of the variable inflammatory response. These 2 processes may in some instances contribute to the same pathophysiologic result. Therefore, the clinical picture *may combine the* features of an exceedingly complex and varied disease of nerve cells and those of a variable inflammatory process in the central nervous system Added to this, one may have the baffling effect of a process *in which recoverable injury of* many nerve cells may be combined with irreversible injury to many others, in many different proportions

It is important to emphasize, moreover, *that although lesions appear in certain* functional centers in the central nervous system, symptoms attributable to such injury need not necessarily result. Such injury must reach a certain threshold of severity, varying with

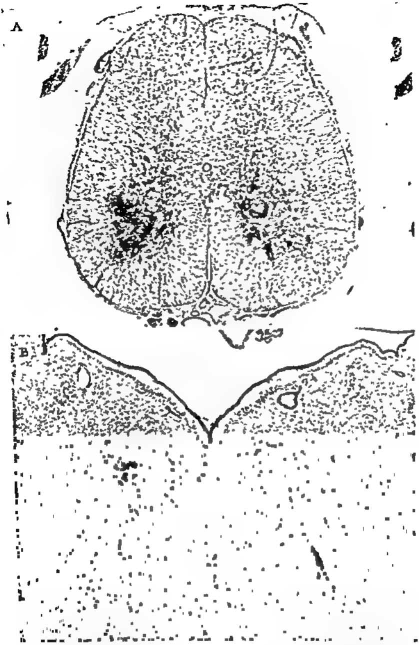

Fig. 66. Focal tissue breakdown in poliomyelitis Gallocyanin stain. (A) Small softening in lumbar cord of severely paralyzed rhesus monkey (C903), 30 days after onset of paralysis. (×20) (B) Medulla oblongata of human case, showing intense reaction in hypoglossal nuclei. On the left side the tissue has broken down in the center of the lesion Case H38, 6 days after onset of paralysis Such lesions are always small and rarely numerous (×20)

FIG 65. Photomicrographs of human spinal cords, showing that the usual association of severe inflammatory lesions with extensive nerve cell destruction does not always occur. Gallocyanin stain (×30) (A) Severe motoneuron loss in posterior part of anterior horn, with very slight inflammatory reaction Case H37, lumbar cord, 3 days after onset of illness (B) Severe focal, diffuse and perivascular infiltrations of lymphocytes and histiocytes, with most anterior horn cells relatively intact in appearance. Case H34, lumbar cord 12 days after onset of illness.

Severe inflammatory reactions in poliomyelitis are usually but not always associated with extensive nerve cell destruction (Fig. 65). In some cases, especially in the brain stem, the inflammatory response in small areas may be enormous and associated at times with a small focus of tissue softening (Fig. 66). Occasionally, a small vessel in such an area may rupture, producing a petechial hemorrhage These softenings were clearly described by Harbitz and Scheel (1907) and occur only in the severest infections Such softenings are never numerous, are rarely larger than 1 or 2 mm. in size and are not the result of vascular emboli. It is not clear whether they are the result or the cause of the very dense cellular infiltration with which they are always associated It seems doubtful that nerve cell injury or destruction alone is responsible for such an unusual reaction, since

Fig. 66 Focal tissue breakdown in poliomyelitis Gallocyanin stain (A) Small softening in lumbar cord of severely paralyzed rhesus monkey (C903), 30 days after onset of paralysis (×20) (B) Medulla oblongata of human case, showing intense reaction in hypoglossal nuclei On the left side the tissue has broken down in the center of the lesion Case H38, [illegible] days after onset of paralysis Such lesions are always small and rarely numerous (×20)

in many areas of severe nerve cell destruction the inflammatory response is relatively quite mild.

We are still ignorant of those details of the cellular pathologic reaction which might explain the occasional severe inflammatory reaction Ever since the concept of the strict neurotropism of poliomyelitis virus was shaken by the successful cultivation of the virus in non-nervous tissue by Enders and his group (1949), the possibility has suggested itself that the virus, or perhaps some strains of the virus, may multiply in the supporting elements of human nervous tissue, the neuroglia, and by so doing produce more severe tissue damage than is ordinarily seen This idea, as a matter of fact, has been advanced by some neuropathologists However, even if true, it requires the difficult assumption that the neuroglia are involved only in regions of susceptible nerve cells since the distribution of lesions in poliomyelitis is the same for all virus strains and for all primate hosts. It is conceivable that an unusually high concentration of virus in small areas may produce a toxic effect apart from the ordinary pathologic effect of virus multiplication in the nerve cells At any rate, it cannot be assumed without further evidence that focal tissue breakdown is due to the multiplication of the virus in non-neuronal elements of the nervous tissue As a rule, moreover, the focal tissue breakdown is not a primary factor in producing the paralysis of poliomyelitis, since it follows the period of greatest nerve-cell damage

Another and more subtle way in which the inflammatory reaction might conceivably affect the clinically localizable functions is by temporarily interfering with synaptic transmission by nerve cells which are destined to recover from sublethal virus effects Interference with synaptic transmission by the inflammatory exudate around motoneurons might have the effect of interrupting, perhaps temporarily, the internuncial and direct reflex pathways in variable proportions

An important observation in quantitative studies of experimental poliomyelitis is that in mild cases in the first days of the disease the great majority of cells exhibit a mild degree of diffuse chromatolysis of cytoplasmic Nissl substance (Fig 63B). In the presence of slight weakness of the muscles innervated by such cells, it is clear that neurons in this state are still functional, although synaptic transmission may not be normal. Experimental evidence strongly suggests that the function of infected motor nerve cells disappears only in the stage of severe chromatolysis (Bodian, 1948). The widespread dissemination of virus among the motor nerve cell population occurs as early as the first day of paralysis Motor nerve cells which are affected either are destroyed quickly during the first few days of the disease or undergo slower recovery changes leading to complete morphologic recovery within about a month or two In limbs showing complete paralysis, recovery is, of course, rare, and in such cases it can easily be shown that only about 10 per cent, or less, of the motoneurons have survived Experimental material clearly shows that the degree of nerve-cell destruction alone can account for most of the paralysis in the subacute and early convalescent period and is also correlated with the degree of muscle atrophy In the acute stage the correlation between nerve-cell destruction and paralysis is not quite so high, so that apparently other factors also play a role in producing paralysis One of the most significant, in cases in which paralysis is not complete, appears to be the reversible injury of nerve cells. Although available human material is not adequate for this type of study, a recovery process similar to that of the monkey appears to occur in human poliomyelitis In human cases with a duration of paralytic symptoms longer than 3 days, active neuronophagia is rarely seen In most instances evidence of active destruction of nerve cells, present in earlier cases, is absent. Within a few days after onset almost the entire degenerative phase of motor nerve cells may be terminated, and the virus concentration, previously high, falls abruptly Most remaining cells after the early acute stage show a pattern of cytoplasmic Nissl substance quite different from the diffuse chromatolysis of this period The remaining Nissl substance instead tends to aggregate in heavy masses near the nerve cell membrane, leaving a pale-staining central area in the center of the cell body (Fig. 67). This appearance of central chromatolysis is characteristic of the recovery stages of nerve cells and

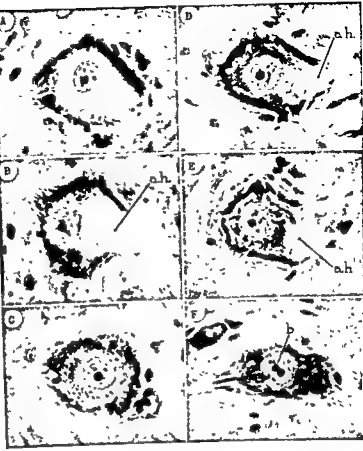

FIG 67. Rhesus B32, ninth day after onset of paralysis. (×500) (A) Severe central chromatolysis, with normal-appearing nucleus and accumulation of heavy masses of Nissl substance near cell membrane Regeneration of Nissl substance may or may not occur near the nuclear membrane. (B-E) Similar cells but with small Nissl bodies in central area. This appearance suggests regeneration of Nissl bodies from the periphery inward, with the area around the axon hillock (a h) last to show recovery (B, D and E) (F) Motoneuron of essentially normal appearance except for presence of acidophilic inclusion body (b) in nucleus In the acute stage such inclusion bodies are seen only in cells with severe chromatolysis, suggesting almost complete recovery of such a cell (Bodian, D, 1949, Poliomyelitis pathologic anatomy in Poliomyelitis. Papers and Discussions Presented at the First International Poliomyelitis Conference, pp 62-84, Philadelphia Lippincott)

has been shown by quantitative studies in monkeys to lead to complete morphologic reconstitution of most recovering cells during the subacute stage of the disease The parallel changes in nerve cells and in virus concentration in the acute and the subacute periods are summarized in Figure 68

In experimental as in human cases, anterior horn cells may be destroyed either in large groups or in scattered fashion over a period of only a few days Motor nerve fibers begin to degenerate about 3 days after destruction of their nerve cell bodies of origin and show typical morphologic changes as well as the time course of secondary or Wallerian degeneration The resulting muscle atrophy follows the time course seen, for example, in Wallerian degeneration due to nerve section, and in cases of severe paralysis is clinically visible within 1 or 2 weeks after onset of paralysis

DISTRIBUTION OF LESIONS IN THE CENTRAL NERVOUS SYSTEM

In spite of the variation in intensity of lesions which occurs in different parts of the central nervous system, partly as a result of the factors just mentioned, the over-all pattern of virus multiplication and of lesion distribution in the central nervous system is

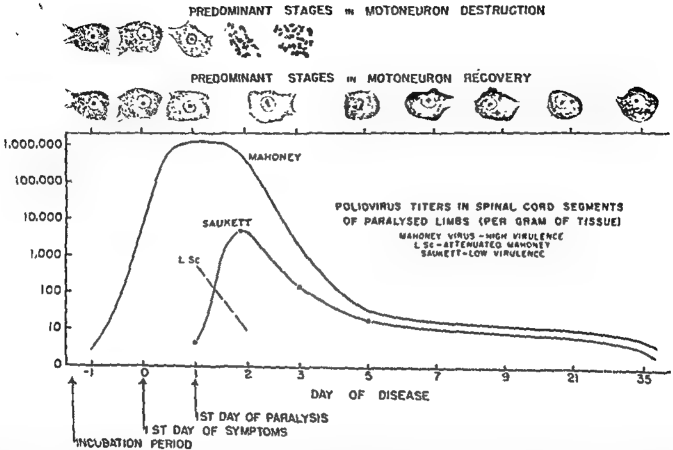

FIG. 68 Schematic representation of the sequence of the cytopathologic stages of motoneurons in the course of destruction and of those chromatolysed but able to recover. The approximate time course of changes is shown with parallel curves showing the trend of rise and decline of viral concentration in the monkey spinal cord. Note that the peak levels of viral concentration are attained at the time when the predominant stage of cell change in the motoneuron population is that of diffuse cytoplasmic chromatolysis Note particularly the low levels of infectivity of the Saukett strain on the first day of paralytic signs, even in spinal cord segments associated with severely paralyzed extremities. Mahoney and Saukett strains were tissue culture adapted strains from routine production of poliomyelitis vaccine (Eli Lilly and Company), and LSc strain was a tissue-culture adapted sample obtained by Dr. Albert B Sabin. (Bodian, D, 1958, Some physiologic aspects of poliovirus infections in The Harvey Lectures (1956-1957), Series 52, pp 23-56, New York, Acad Press)

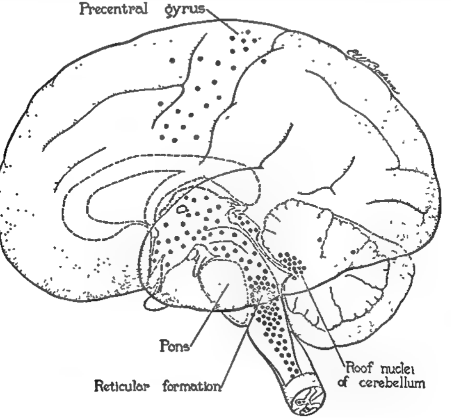
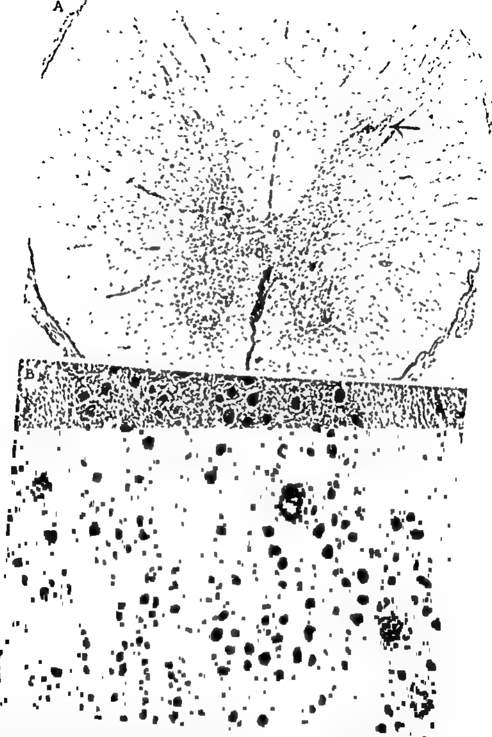
remarkably constant. This pattern, which has been well known since the classic study of Harbitz and Scheel (1907), is quite similar in human poliomyelitis and in experimentally produced infections in monkeys and chimpanzees (Fig. 69) Thus, the clinical forms of poliomyelitis referred to as spinal, bulbar, encephalitic, meningitic and the rare cerebellar or ataxic form are due to a single pathologic picture of lesion type and lesion distribution They differ only in respect to greater severity of destructive and inflammatory lesions in one or another part of the CNS. Within the major pattern of lesion distribution, variation in details occurs In the spinal cord, for example, although some fatal cases exhibit a striking restriction of lesions to the anterior gray columns, other cases may exhibit lesions of varying severity, but usually of spotty distribution, in the intermediate, the intermediolateral and the posterior gray columns (Fig 70) Extension of virus and viral lesions to the sensory spinal ganglia is the rule, but in certain instances in which minimal lesions are present in the spinal cord, no lesions will be found in the sensory spinal



[illegible] central gyrus, and those in the cerebellum to the roof nuclei Lesions are generally found widespread in the brain-stem centers, with a number of striking exceptions, such as the nuclei of the basis pontis, and the inferior olivary nuclei (Bodian, D, 1949, Poliomyelitis pathologic anatomy *in* Poliomyelitis Papers and Discussions Presented at the First International Poliomyelitis Conference, pp 62-84, Philadelphia, Lippincott)



... may be responsible for symptoms of pain and tenderness in poliomyelitis Human case H35, 2 days after onset of disease Gallocyanin stain. FIG 71 Cerebral cortex and hypothalamus of a human case (H12), 9 days after onset of severe paralytic poliomyelitis Gallocyanin stain (A) Precentral gyrus (*right*), and postcentral gyrus (*left*) showing remarkable localization of lesions in precentral (motor) cortex only Lesions of greater severity are rare in fatal cases, and it is doubtful that they contribute significantly to the clinical picture (×5) (B) Hypothalamus at level of paraventricular nucleus (*below*) showing severe perivascular and focal infiltrative lesions Such lesions as well as neuronal lesions are common in fatal cases (×20)

ganglia It is important to note that some parts of the brain are rarely involved to a degree severe enough to suggest that symptoms may result The brain stem, including the hypothalamus and the thalamus, bears the brunt of the cerebral pathologic changes in poliomyelitis, lesions in the cortex, usually mild, are largely confined to the motor cortex (Fig 71) Since this is true of the encephalitic form of the disease, it is clear that the encephalitic symptoms of disorientation, restlessness, somnolence or coma must be due either to intense lesion formation in the upper brain stem, or to cortical hypoxia, rather than to the extensive cortical lesions seen in some of the other viral encephalitides In addition to the variable damage to cranial nerve centers, lesions which are highly variable in severity occur in the rostral and the caudal parts of the brain stem and in the deep cerebel-

FIG. 72. The reticular formation and vestibulocerebellar centers in human poliomyelitis Gallocyanin stain. Lesions as in (A), but especially severe in left vestibular nuclei and in right cerebellar roof nucleus (×5)

lar nuclei (Fig. 72) To these have been ascribed both motor disturbances, such as spasticity, tremor and ataxia, autonomic disturbances, including disorders of respiratory and vasomotor function, and disturbances of sweating The characteristic distribution of poliomyelitis lesions has been shown experimentally to be due to two principal factors: (1) the inherent variation of susceptibility of nervous centers to infection, and (2) the restricted movement of virus along certain nerve fiber pathways.

The distribution of lesions in the brain is essentially the same in nonparalytic cases as it is in severely symptomatic cases. This indicates clearly that symptoms are determined not only by the characteristic distribution of lesions but also by the severity of the lesions,

which varies greatly from case to case, and indeed in different parts of the nervous system of the same case. The relation of lesions in various parts of the brain to particular symptoms has been a subject of considerable interest. In considering this interesting but extremely difficult subject, one may say that variation in severity of lesions in a structure which controls so many diverse functions must necessarily lead to great variation of symptom patterns. The factors determining severity of lesions have not been studied sufficiently. Nevertheless, three general factors are known to affect this important variable. First, it is known from the earliest experimental work that virus strains differ greatly in their capacity to injure or destroy nervous tissue. Although this difference has been shown to be correlated usually with infective titer, it is not clear that this is the only determining factor. Second, it is known that severity of lesions and of symptoms may be reduced due to partial immunity resulting from previous paralytic or nonparalytic infection. Third, experimental work has shown clearly that individual hosts vary considerably in their response to a similar infective dose, even when they have had no previous immunizing experience with the virus. In view of the heterogeneity of the human population with regard to age, sex, nutritional status, endocrinologic make-up and genetic constitution, it is not surprising that all of these factors at one time or another have been explored to explain the variation of host-response. In addition, provoking factors such as trauma, strenuous exercise and certain types of immunizing inoculations must be considered as part of this complex and elusive problem.

DISTRIBUTION OF LESIONS IN RELATION TO DIAGNOSIS

Although the pathologic diagnosis of poliomyelitis is now usually a confirmatory procedure in relation to a typical clinical course, or to positive virologic and serologic findings, it may be of decisive importance in relation to atypical cases, such as instances of death in adults following acute laryngeal paralysis unaccompanied by other telltale symptoms. In such cases, fatal instances of the Guillain-Barre syndrome, or instances of fatal encephalomyelitis in which virus cannot be isolated, the burden of diagnosis leans heavily on the resources of the pathologist.

Often the spinal cord sections alone will serve to distinguish clearly between the possibilities of poliomyelitis and demyelinating disease, Guillain-Barre syndrome, or other neurologic diseases. The differentiation between poliomyelitis and other neurotropic virus diseases may further require analysis of the distribution of lesions in the brain, since spinal cord lesions are similar in many respects in most of these diseases. For this purpose multiple tissue blocks are necessary from the major functional centers of the brain.

The terminal distribution of lesions in the brain, which coincides in general with the virus distribution (Sabin and Ward, 1941), is that of a brain-stem encephalitis. Lesions in the forebrain are confined almost exclusively to the precentral gyrus, or motor cortex (Fig. 71), and the globus pallidus. Occasional cuffed vessels may be found in cortex closely adjoining the motor cortex. The olfactory, visual and auditory centers in the forebrain as well as the hippocampal formation are entirely spared.

The hemispheres of the cerebellum and the corticopontine system from cerebral cortex to pontine nuclei are free of lesions, whereas the cerebellar vermis and the deep cerebellar nuclei are often severely involved. This involvement is associated with heavy lesions in the vestibular nuclei (Fig. 72). Other centers involved in the hindbrain are the reticular formation throughout its extent and motor and sensory nuclei of the cranial nerves. In bulbar poliomyelitis unusually severe lesions are often found symmetrically placed in the region of the nucleus ambiguous on both sides of the reticular formation. Further details may be found by consulting earlier accounts (Bodian, 1947, 1949).

The characteristic distribution of CNS lesions in poliomyelitis infections is also of value in certain aspects of viral diagnosis in experimental primates. For example, in connection with the monkey safety test for poliomyelitis vaccine, the pathologic picture serves to distinguish between CNS infection due to polioviruses and silent infections due

to viruses of simian origin (Technical Committee, 1956).

Poliomyelitis: Control

INTRODUCTION

Although the report (Landsteiner and Levaditi, 1909) that the virus of poliomyelitis was transmitted to an experimental animal was made in 1909, it was not until 1931 that suspicion was expressed concerning the possible existence of more than one immunologic variety (Burnet and Macnamara, 1931). This was soon confirmed by many workers, and in 1949 the differentiation of 3 immunologic types was clearly established (Bodian et al, 1949, Kessel and Pait, 1949). On the basis of findings in a study of 100 strains (National Foundation for Infantile Paralysis, Committee on Typing, 1951), it seemed probable that the development of a procedure for the control of poliomyelitis by immunologic means need be concerned only with the 3 immunologic varieties of virus then known to cause the paralytic disease. More recent evidence suggests that sporadic cases, as well as small epidemics of the poliomyelitis syndrome, including paralysis, are caused by such immunologically diverse agents as Coxsackie and ECHO viruses (see Chaps 25 and 26). Among the 3 immunologic varieties of poliovirus, type I is the principal contributor to the paralytic form of the disease, while all 3 types seem to cause infection equally readily (Salk, 1955a).

Lifelong immunity to paralysis results from natural infection (Paul and Riordan, 1950), and it seems unnecessary to postulate that the maintenance of immunity is due to repeated reinfections. When infantile infection occurs, under the protection of maternal antibody, sustained immunity to paralysis results, but not necessarily immunity to reinfection.

Among the earliest reports on immunization of monkeys, and then of man, were those of Brodie and Park (1936) and Kolmer (1936). Their studies were conducted before precise knowledge of immunologic complexity was available. More than a decade later, Morgan (1948) clearly demonstrated that a formaldehyde-treated suspension of central nervous system tissue from monkeys containing a type II strain of poliovirus caused the formation of appreciable quantities of antibody. She was also able to induce a measurable degree of resistance to intracerebral challenge in monkeys vaccinated with similarly prepared type I virus. A number of other investigators (Loring et al, 1947, Milzer et al, 1945, Schwerdt et al, 1951) in studies with mice and cotton rats, confirmed the fact that preparations of type II virus that were noninfectious were still capable of inducing immunity in rodents. These studies indicated that materials devoid of demonstrable infectious activity for animals will immunize if given repeatedly in sufficient amount.

This approach was extended by Howe (1952) who was able to demonstrate antibody formation in chimpanzees. In parallel experiments in 6 human subjects he observed the development of antibody that in most in-

stances persisted over the observation period of 6 months.

The discovery by Enders et al. (1949) of the cultivation of poliovirus in various human embryonic tissues, and the independent observation of Smith et al (1950) of the growth of polioviruses in culture of human testicular tissue, initiated and stimulated studies that led to the demonstration in monkeys and then in man (Salk et al 1953) of the antigenic activity of formalin-treated virus grown in tissue culture, and the later demonstration (Francis et al, 1957) of the protective effect of formalinized vaccine (Salk, 1955b) prepared from virus propagated in cultures of monkey kidney tissue

In another approach for inducing immunity, first tested in humans by Koprowski et al (*1952*), they reported the results of studies in 20 human subjects fed an attenuated live type II virus which had been propagated in the CNS of rodents Evidence was found of virus multiplication in the gastro-intestinal tract, and an immunologic response occurred The agent used for feeding was less pathogenic for the monkey than for rodents, but still caused paralysis when inoculated intracerebrally into the monkey Studies with virus that had undergone greater degrees of attenuation have been further extended by Koprowski (1957) and by Sabin (1957)

A fuller historical account of studies on immunology and immunization against poliomyelitis is presented by Boyd (1953, 1957), and the reader is referred to these well-documented sources The following sections deal with the substance of recent studies that bear directly upon the control of poliomyelitis by immunologic means.

Passive Immunization

That it is possible to induce passive immunity artificially, simulating the effect of passively transferred maternal antibody, was demonstrated not only in experimental animals (Bodian, 1951) but also in human subjects given large doses of human gamma globulin (Hammon et al, 1953) Although a clearly demonstrable effect was induced in a carefully controlled field trial and revealed that a low level of antibody was effective in prevention of paralytic polio, the procedure proved to be impractical for general use because of the large amounts of gamma globulin required for so many potential susceptibles who might not be exposed, and the relatively short period of duration of gradually diminishing effect in relation to the uncertainty of time of exposure.

Active Immunization

That it should be possible to induce lifelong immunity to paralysis by artificial means is suggested by the fact that immunity of this degree develops under natural circumstances (Paul and Riordan, 1950). On the basis of known immunologic principles and experience, two approaches could be considered: (1) the use of orally administered attenuated virus for inducing infection and simulating the natural immunizing process, and (2) the use of a noninfectious virus preparation for inducing the formation of circulating antibody and, [illegible]

of considerable discussion, both theoretical and practical, and because all issues have not been fully resolved and are broadly related to the problem of the control, not only of poliomyelitis but also of other virus diseases, each will be considered in detail

Before doing so it might be well to point out certain conceptions that have prevailed which have influenced thought and the direction of experimentation. It is a fact that the [illegible]

low fever). It does not necessarily follow, [illegible]

the effective immunologic control of any virus disease be brought about The evidence suggesting that immunity induced by killed-virus vaccines is sometimes less substantial and less durable than that resulting from infection does not necessarily mean that the critical elements for solid and durable immunity cannot be created by a noninfectious preparation suitably prepared and suitably administered

LIVE-VIRUS VACCINE

Prerequisites

The prerequisites for a live-virus vaccine for poliomyelitis are: (1) *biologic attenuation* of virulence before human use, and (2)

knowledge of the degree of stability of the attenuated form when released in the human population It is self-evident that the application of such a procedure must be without risk to the treated individual, to his immediate contacts and to the community beyond

A very considerable body of experimental data has been developed by Koprowski (1957) and by Sabin (1957) and by others on attenuation of virulence by various biologic devices for segregation and propagation of relatively avirulent virus populations The reader is referred to the work of these investigators for a full account of the technics employed and the results obtained in effecting a reduction in virulence for the CNS of laboratory primates Although there is not full agreement upon the degree of attenuation to be achieved before application of attenuated polioviruses in experiments involving increasing numbers of human subjects, the evidence deduced by Koprowski and Sabin, and others, in several hundred persons over a period of several years, has revealed no harmful effect However, a return of virulence for primate CNS was shown in tests of the excreted virus, in a number of instances at least (Sabin, 1957, Dane et al, 1957, Dick et al, 1957, Dick and Dane, 1957) Moreover, it was shown that virus spread to contacts (Dane et al, 1957, Dick et al, 1957, Dick and Dane, 1957; Paul et al, 1957) Some of these studies have also shown that a degree of attenuation could be achieved that would result in retention of infectivity for tissue culture, but reduced capacity to multiply in the human alimentary tract (Sabin, 1957) Such strains also failed to immunize Thus, retention of power to infect is accompanied by the power to multiply and to spread to contacts and has been associated with the possibility of reappearance of forms virulent for the CNS of laboratory primates (Sabin, 1957) The significance of these findings, particularly in relation to the question of the limitations within which such preparations are safe for the individual or the community, cannot possibly be resolved without direct test in large numbers and under circumstances that would avoid possible confusion of results by the activity of naturally occurring polioviruses It would be necessary to evaluate the effects of intangible factors of time and season, as these bear on the appearance of virulent forms selected from the naturally predominantly avirulent forms, and the phenomenon of mutation of the artificially attenuated viruses

The problem posed by the possible use in man of a live-virus vaccine for poliomyelitis is somewhat different from that of a live-virus vaccine for smallpox or yellow fever In the instance of attenuated yellow fever virus, there is less risk of person-to-person transmission, without a mosquito vector, and the duration of virus carriage in the inoculated host is sharply limited. This is quite different for poliovirus in man where both naturally occurring and artificially administered viruses have been shown to be present, in many instances for many weeks, in the human gastrointestinal tract In the case of smallpox, it appears that vaccinia virus, which has limited capacity to spread (except in such instances as persons with eczema) and limited persistence in the vaccinated individual, has stable pathogenic properties

In view of the demonstration that it is possible to induce immunity to paralytic poliomyelitis by means of a killed-virus vaccine, and in view of the implications of the foregoing, some have questioned the reasonableness of the live-virus vaccine approach The principal incentive for continued interest in the possible usefulness of a live-virus vaccine (Paul et al, 1957) resides in the unresolved question concerning the duration of immunity that it is possible to achieve with a killed-virus preparation Additional reasons are related to ease of oral administration and possible economy of material if smaller amounts of live-virus can be employed than are required for injection of killed antigen It has been proposed that the feeding of attenuated viruses might ultimately exclude virulent virus from circulation (Koprowski, 1957, Fox, 1957).

It is difficult to follow the reasoning that an attenuated live virus might exclude virulent viruses from circulation in the population inasmuch as the basis for the relationship between virulent and avirulent forms in nature is not known It is also difficult to understand how the eradication of poliovirus infection from a population would be effected by the use of a live-virus vaccine when this has

not occurred under circumstances of a high immunity index in areas of poor hygiene and high infection rate but low paralytic rate. Since the reservoir of infection would be maintained artificially by inducing infection in the newborn, it is to be expected that the paralytic rate in the population would be less than in the absence of the application of some method of artificial immunization early in life

There is no reason to question the probable high order of effectiveness of the immunizing potential of a live-virus vaccine. Some have expressed the view that if all persons throughout the world could be fed the same type of attenuated, live-poliovirus on the same day, the question of possible risk to contacts would be obviated, and the risk of future newborn could be obviated by early feeding of live-virus while maternal antibody is still present in protective amounts

Since this has not yet been accomplished, and since it is highly improbable that this could be done, then the questions posed concerning the practicability of a live-virus vaccine, for a disease with the characteristics of poliomyelitis, still remain to be answered.

KILLED-VIRUS VACCINE

Prerequisites

The essential prerequisites for an effective immunizing procedure, using a killed-virus vaccine, are: (1) a practicable source of virus for conversion into vaccine; (2) a reliable method for destroying infectivity while retaining antigenicity; and (3) a practicable way for inducing an effective degree of immunity that is sufficiently long-lasting

Source of Virus

The demonstration by Enders, Weller and Robbins (Enders et al, 1949) that poliomyelitis viruses can be propagated in a variety of human and simian tissues was a key factor in providing the basis for a source of virus for vaccine, and for the development of simplified technics for measuring both virus and antibody activity. The availability of antibiotics provided the basis for overcoming one of the principal obstacles to mass tissue cultivation and in vitro testing The finding that monkey kidney tissue cultures provided a rich source of virus permitted the rapid extension of early observations that virus grown in tissue culture could be rendered noninfectious and still retain antigenic power (Salk et al., 1953).

It is probable that continuously propagating cell-lines will ultimately be used as a source of virus for poliomyelitis vaccines and will eliminate dependence on monkeys for the cell substrate upon which virus for vaccine is propagated

Reliable Method of Killing

The conversion of the live-virus to a noninfectious form can be effected by treatment with formaldehyde. In the presence of a 1:4,000 dilution of formalin at pH 7 and at 37° C. the reaction is essentially complete in less than 1 week; but, in general, from 3 to 5 days of additional treatment is applied. The killing process is readily completed, with an adequate margin of safety, if the raw tissue culture fluid is first clarified by filtration for removal of particles that might contain entrapped virus that could not make effective contact with formaldehyde (Salk et al, 1954 and 1955; Salk, 1956b)

The indication that the inactivation of polioviruses, by formaldehyde, is an orderly and predictable phenomenon suggested that the inactivation procedure could be amenable to the kind of control that would permit reliably reproducible destruction of infectivity, with retention of antigenicity (Fig 73).

The importance of understanding the na-
ture of the [illegible]

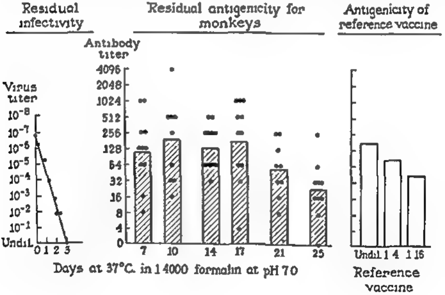
infectious virus exists in a vaccine preparation is so high as to provide practicable assurance that complete inactivation has, in fact, taken place In practice, the controls for vaccine preparation are as follows: Samples are removed at intervals to reveal the rate of loss of infectivity with time; residual virus infectivity is plotted on a logarithmic scale, and time on an arithmetic scale This is done to indicate that a sufficient amount of free-formaldehyde is present in the particular reaction vessel to cause the inactivation to proceed in the expected manner. Overtreatment is then applied, for a sufficient margin of safety, to increase the probability that the entire contents of the vessel are rendered noninfectious. Samples for safety test are removed after the process is completed. If the results

of tests upon such samples are negative, and if this occurs consistently in consecutive lots, this indicates that a reproducible method is available, and it provides a basis for reasonable expectation that each dose of each lot, so prepared and tested, is equally free of infectious virus

In the event that the measurable portion of the line describing the course of the inactivation reaction proceeds as expected, and if, in relation to the data on rate of inactivation, the safety test samples are positive when theoretically they should be negative, a clue is provided that something is awry (Salk, 1956b). Wherever such difficulties have been encountered in failure to inactivate virus consistently, it has been found that this can be rectified by the use of a suitable system of clarification and filtration for removal of particles that contain virus protected from contact with formaldehyde (Bodian et al, 1955, Salk, 1956b, Salk, 1957a) It is now well established that in practice, as well as in theory, safe vaccine can be prepared consistently (Bodian et al, 1955; Bodian, 1958).

It was reported originally that inactivation of poliovirus proceeds as does a first-order reaction (Salk et al, 1954; Salk et al, 1955) There is considerable evidence suggesting that the inactivation is essentially first-order (Salk, 1957a, Bodian, 1958) as has been demonstrated in a number of laboratories However, the experience of others indicates deviations from a straight line at either the beginning (Timm et al, 1956) or at the end (Gard and Lycke, 1957) of the measurable portion of the inactivation curve These differing experiences have not yet been reconciled.

Attempts have been made to use ultraviolet light for destroying infectivity of poliovirus for vaccine, however, too great loss in antigenicity occurs after sufficient treatment for destruction of infectivity Ultraviolet light has been used in conjunction with formalde-



of Reference Vaccine A These data are for the Saukett strain of type III virus (Salk, J E., 1957, Viral and cellular factors pertinent to control of paralytic poliomyelitis with a noninfectious vaccine *in* Cellular Biology, Nucleic Acid and Viruses (Special Publication), vol. 5, pp 77-89, New York Acad Sc.)

not occurred under circumstances of a high immunity index in areas of poor hygiene and high infection rate but low paralytic rate. Since the reservoir of infection would be maintained artificially by inducing infection in the newborn, it is to be expected that the paralytic rate in the population would be less than in the absence of the application of some method of artificial immunization early in life

There is no reason to question the probable high order of effectiveness of the immunizing potential of a live-virus vaccine. Some have expressed the view that if all persons throughout the world could be fed the same type of attenuated, live-poliovirus on the same day, the question of possible risk to contacts would be obviated, and the risk of future newborn could be obviated by early feeding of live-virus while maternal antibody is still present in protective amounts

Since this has not yet been accomplished, and since it is highly improbable that this could be done, then the questions posed concerning the practicability of a live-virus vaccine, for a disease with the characteristics of poliomyelitis, still remain to be answered

KILLED-VIRUS VACCINE

Prerequisites

The essential prerequisites for an effective immunizing procedure, using a killed-virus vaccine, are. (1) a practicable source of virus for conversion into vaccine; (2) a reliable method for destroying infectivity while retaining antigenicity, and (3) a practicable way for inducing an effective degree of immunity that is sufficiently long-lasting.

Source of Virus

The demonstration by Enders, Weller and Robbins (Enders et al, 1949) that poliomyelitis viruses can be propagated in a variety of human and simian tissues was a key factor in providing the basis for a source of virus for vaccine, and for the development of simplified technics for measuring both virus and antibody activity. The availability of antibiotics provided the basis for overcoming one of the principal obstacles to mass tissue cultivation and in vitro testing The finding that monkey kidney tissue cultures provided a rich source of virus permitted the rapid extension of early observations that virus grown in tissue culture could be rendered noninfectious and still retain antigenic power (Salk et al, 1953).

It is probable that continuously propagating cell-lines will ultimately be used as a source of virus for poliomyelitis vaccines and will eliminate dependence on monkeys for the cell substrate upon which virus for vaccine is propagated.

Reliable Method of Killing

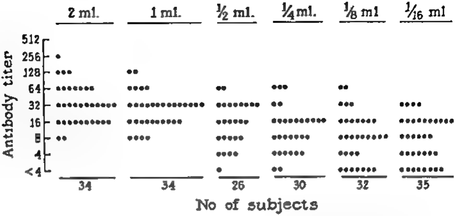
The conversion of the live-virus to a noninfectious form can be effected by treatment with formaldehyde. In the presence of a 1:4,000 dilution of formalin at pH 7 and at 37° C. the reaction is essentially complete in less than 1 week; but, in general, from 3 to 5 days of additional treatment is applied The killing process is readily completed, with an adequate margin of safety, if the raw tissue culture fluid is first clarified by filtration for removal of particles that might contain entrapped virus that could not make effective contact with formaldehyde (Salk et al, 1954 and 1955, Salk, 1956b)

The indication that the inactivation of polioviruses, by formaldehyde, is an orderly and predictable phenomenon suggested that the inactivation procedure could be amenable to the kind of control that would permit reliably reproducible destruction of infectivity, with retention of antigenicity (Fig 73).

The importance of understanding the nature of the inactivation reaction, for establish- [illegible] of safety is to provide

infectious virus exists in a vaccine preparation is so high as to provide practicable assurance that complete inactivation has, in fact, [illegible]

time on an arithmetic scale. This is done to indicate that a sufficient amount of free-formaldehyde is present in the particular reaction vessel to cause the inactivation to proceed in the expected manner. Overtreatment is then applied, for a sufficient margin of safety, to increase the probability that the entire contents of the vessel are rendered noninfectious Samples for safety test are removed after the process is completed If the results



[illegible] antibody to any type prior to Reference Vaccine A given [illegible] The fractional amounts of [illegible] ml injection. (Salk, J E, 1955, Considerations in the preparation and use of poliomyelitis virus vaccine, J A M.A. *158*, 1239-1248)

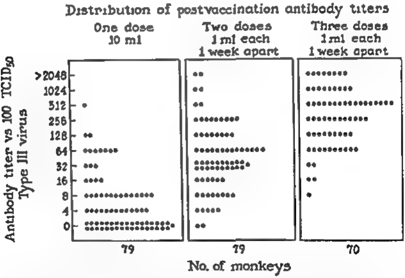


FIG 76 Comparison of antibody response to multiple doses and a single large dose as tested in monkeys Each symbol represents the antibody level for type III virus in 1 monkey injected either with 1 10-ml dose or 2 doses of 1 ml each a week apart or 3 doses of 1 ml. each a week apart (Salk, J E, 1955, Studies with noninfectious poliomyelitis virus vaccines *in* Poliomyelitis: Papers and Discussions Presented at the Third International Poliomyelitis Conference, pp 167-185, Philadelphia, Lippincott)

hyde (Taylor et al., 1957), but there is no evidence that this is either necessary or advantageous

Factors of Importance for Inducing an Antigenic Effect with a Noninfectious Vaccine

It is possible to destroy infectivity completely, with full retention of antigenic activity (Salk, 1957a) Loss of antigenic substance in the course of vaccine manufacture and processing can occur through removal of antigen by filtration, or through excessive destruction by the chemical or physical factors employed for destroying infectivity, or by the use of certain preservatives of sterility that deleteriously affect antigen stability. The degree of antibody response elicited in experimental animals and in man is related to the 3 fundamental factors: (1) potency of the antigen administered, (2) number of injections and (3) spacing between injections. These and other factors that influence the formation and the persistence of antibody will be discussed in relation to the question of the mechanism of immunity and the control of the disease.

Normal Biologic Variation

In considering the influence of quantity of antigen upon degree of antibody formation, cognizance must be taken of the relatively wide degree of variation in individual response not only among human subjects but in experimental animals as well This is only another example of normal biologic variation and emphasizes the expectation that some individuals will react with antibody formation to the injection of small quantities of antigen whereas other individuals will not respond. The basic factors responsible for the absence of uniformity in responsiveness is beyond the scope of the present considerations However, the fact itself is of fundamental importance because the degree of effectiveness of any procedure employed for artificial immunization must consider the extremes of variation likely to be encountered.

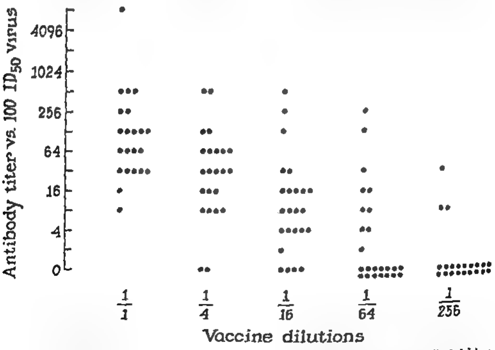

FIG. 74. Antibody response in groups of monkeys vaccinated with diminishing dilutions of Reference Vaccine A. Three doses were given intramuscularly at weekly ... third dose. Each symbol represents ...ent of Reference Vaccine A. (Salk, ...use of poliomyelitis virus vaccine,

ployed was occurring as the interval between injections was prolonged (Salk, 1955b).

Factors Related to Practical Application

The translation of these observations into practical application must consider the length of the interval between the first injection and the time when it is desired that a satisfactory degree of immunity is engendered (Salk, 1956c and 1957b) It would seem from the foregoing that, within certain limits, any desired effect could be achieved by adjusting vaccine potency, number of injections and spacing between injections For example, if a 1-dose procedure were desired, a greater potency of vaccine would be required to induce the formation of a selected mean level of antibody, or conversion of a certain proportion of persons from negative to positive antibody status, than would be required to achieve the same level of antibody response if vaccine is given on a 2- or a 3-dose schedule Furthermore, the requirements for potency would be less if intervals between injections are longer rather than shorter. The greatest assurance of maximal effect would be provided by vaccine at a level of potency that would be expected to effect conversion from negative to positive antibody status (i e, titer of 1:4 or > vs 100 ID_{50} of virus) in almost all persons after 2 doses of vaccine, separated by an interval of 1 month, allowing a third dose, some months later, to provide a further margin for full effectiveness, as well as the booster effect.

Effect of Intensity of Primary Sensitization upon Degree of Response to Booster

Another factor that determines the level of antibody that can be induced by a killed-virus vaccine is the degree of primary antigenic stimulation Figure 79 reveals the response to a fixed dose of vaccine administered as a booster injection in groups of individuals treated earlier with graded doses of Reference Vaccine A It is evident that the response to the booster dose is influenced not only by the size of this dose (Salk, 1955b)

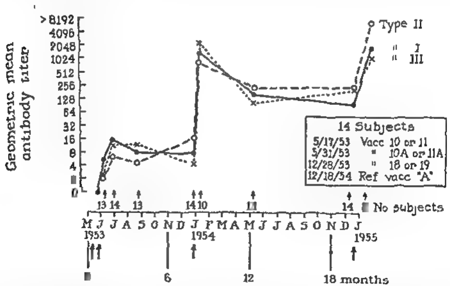

Fig 78 Illustration of "booster" response to third dose given approximately 7 months after 2 primary injections spaced 2 weeks apart Geometric mean antibody titers in 14 children who possessed no discernible antibody prior to injection. Degree of persistence after third dose and response to a fourth dose administered 1 year later are illustrated also Number of subjects available for serologic study at each point in time is shown above the time scale (Salk, J E, 1955, Considerations in the preparation and use of poliomyelitis virus vaccine, J A M A. *158, 1239-1248*)

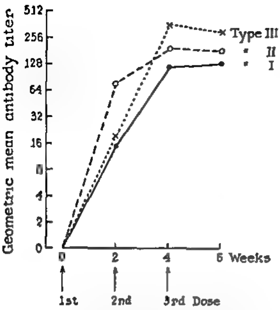

FIG 77. Refractoriness to further increase in antibody titer after third injection of series of 3 at 2-week intervals Each symbol represents mean for 20 individuals. (Salk, J. E. 1955. Considerations in the preparation and use of poliomyelitis virus vaccine, J.A.M.A *158*, 1239-1248)

EFFECT OF ANTIGEN DOSE

The influence of dose upon antibody response and the effect of variation in responsiveness among monkeys is shown in Figure 74 The levels of antibody observed in individual animals 1 week after the last of 3 weekly injections are shown The lack of uniform response at each dosage level is clearly evident The effect of quantity of antigen upon degree of response is shown Similar observations have been made in groups of children who had no detectable antibody to any type prior to injection This is shown in Figure 75. In this instance, 2-fold dilutions of vaccine are compared, and the response shown is that observed 2 weeks after a single 1 ml dose containing the indicated quantity of stock reference vaccine It is clearly evident that some individuals, both among monkeys and human subjects, react less readily to the same dose of vaccine than do others, and that by increasing the quantity of antigen administered, it is possible to raise the proportion of those who do respond so that above a certain minimal level of antigen it can reasonably be expected that all, or almost all, will respond—except for those who may have a defect in their immunologic mechanism

EFFECT OF SINGLE VS. DIVIDED DOSES

Data in Figure 76 are presented to illustrate the advantage of small divided doses, at intervals, as compared with a single large dose. The antibody response in monkeys, after 2 or 3 doses of vaccine of 1 ml. each, given a week apart, is compared with the level of antibody induced by 10 ml of vaccine given in a single dose.

EFFECT OF LENGTH OF INTERVAL BETWEEN INJECTIONS

The effect upon antibody response of the length of the interval between injections is illustrated by a comparison of Figures 77 and 78 Figure 78 reveals that 3 doses in man was not as efficient, when given over a 4-week period, as was spacing extended over a 7-month period. There is a period of relative refractoriness to further antibody response early after primary immunization, this is then followed by the development of a markedly hyper-reactive state. The length of the interval required for the development of the hyper-reactive state differs in different animals. The interval required in man is longer than in the monkey; and in this animal it is longer, in turn, than in small laboratory animals such as guinea pigs and mice Although the precise reasons for these differences are not clear, they may well be linked to the rate of metabolism and rate of maturation in the respective species. Although systematic studies are incomplete, the results in man suggest the advantage of longer rather than shorter intervals; and, in 4 to 5 months, after a single injection (Salk, *1955b*), some degree of hyper-reactivity is evident in most individuals It is probable that the point in time when the hyper-reactive state is developed varies from person to person Since it is not possible to study this phenomenon in a single individual, the result of such a study in sufficiently large groups of individuals could be expected to reveal a gradual change approaching a plateau. Such observation was made in an experiment the final interpretation of which is limited by the fact that some degree of deterioration of the vaccine em-

Group A, but a lesser proportion of individuals had demonstrable antibody 1 year later. The effects observed for the types II and III component of the vaccine were more substantial, and the degree of persistence was greater The conclusion to be drawn is that the level and the degree of persistence of antibody after the booster is related, in part, to the intensity of antigenic stimulation

From the experience with the type II and type III components of the vaccines used in this study, it appears that another factor that plays a role in determining the efficiency of antibody formation and persistence is the quality of the antigen of the particular strain of virus used for conversion into vaccine. It is generally true that different antigenic substances possess different degrees of antigenic capacity—some are good antigens, and others are inferior. However, the same quantitative factors play a role in determining the response that can be achieved within the limits of capacity of any particular antigen.

The course of antibody rise and decline is illustrated in Figure 81. Observations made over a 3- to 4-year period (Salk, 1958) in-

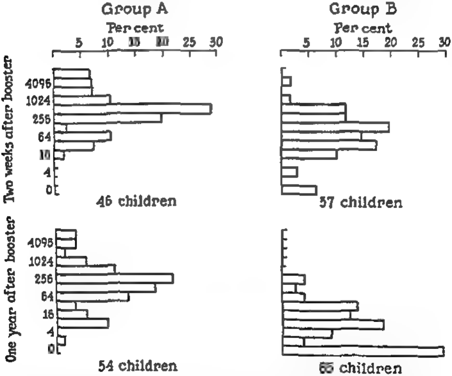

FIG 80 Distribution of type I antibody titers 2 weeks after booster injection, and again 1 year later. Comparison between 2 groups treated as follows

GROUP A Individuals given 2 doses 2 weeks apart, containing the following volumes of Reference Vaccine A. 2 ml, 1 ml or ½ ml This was followed 1 year later by "booster" dose of 1 ml. of Vaccine J essentially similar in potency to Vaccine A

GROUP B Individuals treated essentially the same way as those of Group A, except for the volumes of Reference Vaccine A used for each of the first 2 doses, which were ¼ ml, ⅛ ml. or ⅟₁₆ ml. (Salk, J E, 1958. Basic principles underlying immunization against poliomyelitis with a noninfectious vaccine *in* Poliomyelitis Papers and Discussions Presented at the Fourth International Poliomyelitis Conference, Philadelphia, Lippincott)

but also by the intensity of the primary immunologic experience. Thus, children given 2 ml. of Vaccine A for each primary injection responded to 1 ml. of Vaccine J with more antibody than did those given $\frac{1}{16}$ ml of Vaccine A for each dose of the initial treatment Figure 79 also presents, for comparison, levels of antibody induced by natural infection It illustrates that, depending upon the potency of vaccine used, the number of doses, and the length of the intervals between injections, the level of antibody induced artificially can equal or even exceed that resulting from natural infection.

Factors Affecting Degree of Persistence of Antibody

It is clear from the foregoing that any statement concerning the comparative antibody response to a killed-virus vaccine versus a live-virus vaccine would have to take cognizance of the potency of the killed-virus vaccine and the number and the spacing of injections. These factors influence not only the level of antibody induced but also the degree of antibody persistence.

Data in Figure 80 reveal that a decline in type I antibody level occurred in the course of a year following the booster dose in groups given vaccine of the degree of potency administered in Group A; however, at the end of the year, all individuals still possessed a demonstrable level of circulating antibody (Salk, 1958). A different situation is illustrated in Group B given a less potent antigen for primary stimulation, but the same dose as Group A for the booster; not only was there a lesser response as compared with

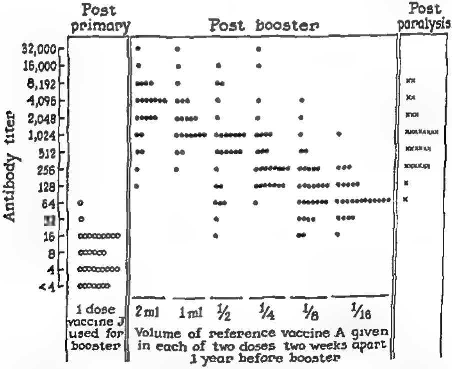

Fig. 79. Effect of amount of antigen used for primary immunization upon antibody response to "booster" dose, and comparison with antibody titer following natural infection Center portion of chart illustrates response of individuals 2 weeks after 1 dose of Vaccine J and shows the effect upon the booster response of the amount of antigenic stimulation at the time of primary immunization. The effect of 1 dose of Vaccine J (1 ml I M.) in children not previously treated with vaccine is shown in the frame on the left, and antibody levels in the convalescent phase of paralytic infections are shown in the frame on the right. (Salk, J E., 1957, Poliomyelitis vaccination in the fall of 1956, Am. J. Pub Health 47, 1-18)

Group A, but a lesser proportion of individuals had demonstrable antibody 1 year later The effects observed for the types II and III component of the vaccine were more substantial, and the degree of persistence was greater The conclusion to be drawn is that the level and the degree of persistence of antibody after the booster is related, in part, to the intensity of antigenic stimulation

antibody formation and persistence is the quality of the antigen of the particular strain of virus used for conversion into vaccine It is generally true that different antigenic substances possess different degrees of antigenic capacity—some are good antigens, and others are inferior. However, the same quantitative factors play a role in determining the response that can be achieved within the limits of capacity of any particular antigen

The course of antibody rise and decline is illustrated in Figure 81 Observations made over a 3- to 4-year period (Salk, 1958) in-

Type I antibody levels after 1 dose of vaccine in children with different prevaccination antibody patterns to illustrate significantly greater type I response in individuals who have had a prior type II infection in comparison with a lesser response in individuals who have had a prior type III infection.

+ = Antibody demonstrable before vaccination at titer of 1:4 or > as determined by color test for antibody measurement in tissue culture (Salk, Youngner, Ward, 1954)

(Salk, J. E., 1956, Requirements for persistent immunity to poliomyelitis, Am.J M.Sc. *232*, 369-377)

dicate that the relatively more rapid decline after the postinjection peak is followed by a very gradual decline or a plateau This suggests that antibody could be expected to be present for several years at least in persons in whom a sufficient degree of antigenic stimulation was once induced The full length of such persistence will be established in time

Effect of Prior Immunologic Experience

It is to be expected that persons who have had a prior natural infection would respond to vaccination with much higher levels of homotypic antibody than would others who had had no prior experience with the antigen in question Figure 82 illustrates the greater response to the type I component of the vaccine in persons with pre-existing type I antibody as compared with others with no prior antibody to any of the 3 types Figure 82 also illustrates the rather unexpected finding that individuals who, prior to vaccination, have only type II antibody from a natural infection, respond with the formation of higher levels of antibody to the type I component of the vaccine than do individuals who have had a prior type III infection (Salk, 1955a, 1956a) These data clearly suggest that the type II viruses that were the cause of these infections had sensitized the immunologic mechanism to type I antigen The response in persons in whom type III infections had occurred previous to vaccination revealed such effects to only a very slight degree. From these and other data it appears that a significant degree of cross relationship exists between types II and I, and types II and III, and to a lesser degree or none at all, between I and III. It is clear from such observations, which have been confirmed (Francis et al, 1957), that a prior natural infection facilitates the formation of antibody not only for the prior infecting type but for other types in proportion to the degree of cross relationship

Observation of Antibody Response in Large Groups and Exceptional Effects

The extent to which antibody formation has been induced in a large group of human subjects is revealed by a study involving a population of 4,617 children, 847 of whom had no demonstrable antibody to any of the 3 types, at a screening level of 1 64 (Salk, 1956c) This was determined by a test performed on capillary blood obtained from a finger-prick After 3 doses of vaccine with an interval of 2 weeks between first and second doses and approximately 1 year between the second and third doses, 803 of the 847 had antibody levels of 1 64 or greater for

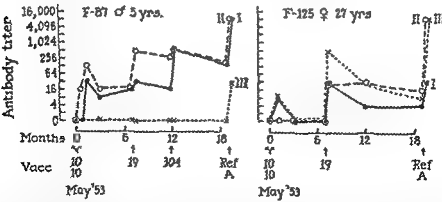

Fig 83 Individual variation in response to the 3 antigens The relatively poor response to type III, illustrated in the case of this particular child, is contrasted with the relative poor response to type I in this particular adult (Salk, J E, 1958, Basic principles underlying immunization against poliomyelitis with a noninfectious vaccine in Poliomyelitis· Papers and Discussions Presented at the Fourth International Poliomyelitis Conference, Philadelphia, Lippincott)

all 3 types, of the remaining 44, all reacted with antibody formation to a level of 1:64 or greater for type II, and lower levels of antibody for types I and III were present in all but one instance It is clear from these observations that all of the children involved were capable of forming antibody if stimulated by a sufficient concentration of antigen The lesser response to types I and III reflect, in these instances, lesser antigenic potencies of the types I and III components of certain of the lots of vaccine involved in this study

In the course of extensive serologic studies involving about 15,000 persons, mostly children but including some adults, rare instances have been observed in which an individual appears to be poorly responsive, or relatively refractory, to 1 of the 3 antigenic components of the vaccines employed The reasons for these unusual effects are not clear, but the facts are illustrated in Figure 83 Here it may be seen that a child who responded well to types I and II, but not to type III, reacted differently from another individual who reacted poorly to type I but appeared to react in the expected fashion to the type III component to which the child was nonreactive The same lots of vaccine were not used throughout the course for both individuals, but there was sufficient similarity for this comparison These extreme examples may reflect either an inborn or an acquired refractoriness to certain antigens, possibly based on the same mechanism as similar examples in other antigen systems

IMMUNOLOGIC FACTORS INVOLVED IN THE IMMUNITY MECHANISM

From the nature of the pathogenesis of the paralytic disease, it is readily understandable that antibody in the serum would be effective in protecting the central nervous system from invasion by virus and in this way prevent paralysis. However, there are some individuals in whom paralysis does not occur even though specific serum antibody was not present before exposure to infection In such instances it might be said that the virus may have been essentially noninvasive. However, certain observations provide a basis for doubt that this is the full explanation The first observation to arrest attention is the greater frequency with which type I paralytic polio occurs in persons who have had an earlier type III infection, as compared with individuals who have had a prior type II infection (Salk, 1955a; 1956a; Hammon, and Ludwig, 1957). The mechanism for protection against paralysis could be the result of the presence of type I antigen in type II viruses (Melnick, 1955) and due to the effect of nondemonstrable type I antibody in the serum, as sometimes does appear in convalescence from type II infections in man (Sabin, 1952). However, the fact that type I antibody activity may not be readily demonstrable makes it necessary to examine whether or not such activity is actually present and, therefore, whether the foregoing explanation is sufficient. Perhaps other factors may be operative.

Further pursuit of this question is possible because of the observations of the difference in type I antibody response in vaccinated persons who have had a prior type II infection as compared with those who have had a prior type III infection (Salk, 1955a) Figure 82 illustrates this difference and suggests the existence of significant type I immunologic hyper-reactivity in those who have had a prior type II infection, in comparison with those who have had a prior type III infection The question then arises as to whether or not a relationship may exist between the protective effect against type I paralysis among those who have had a prior type II infection and their heightened reactivity to type I antigen

The phenomenon of immunologic hyper-reactivity, or the booster phenomenon in immunology, is associated not only with a greatly increased production of antibody but also with earlier appearance of greater concentrations of antibody in the serum Regardless of whether the hyper-reactive mechanism results in the more rapid appearance of antibody or merely a greater production, there is the reasonable question as to whether or not heightened immunologic reactivity could play a role in prevention of paralysis, under circumstances where the incubation period before paralysis is such as to permit antibody to be effective in reducing the probability of paralysis. From studies on the pathogenesis

of paralytic polio, Bodian (cf Chap. 23) has pointed out that there is an incubation period of approximately 7 days from exposure to onset of systemic symptoms, and approximately 5 days between them and onset of neural symptoms This suggests an interval of between 7 and 12 days from exposure to the initiation of CNS infection MacLeod (1953) has proposed a theory to explain lifelong immunity in certain infectious diseases and not in others He has reasoned that the earlier appearance of effective concentrations of antibody in an individual who has had a prior immunologic experience, coupled with a sufficiently long incubation period to allow this effect to be operative, could explain lifelong immunity to diseases of long incubation and relatively short-term immunity in diseases of short incubation period Whether or not this theory is generally applicable or can be considered to apply in this instance will be established in the course of time

In the light of the foregoing it is interesting to view the observation (Lau et al, 1957) that injections of relatively large amounts of antiserum into monkeys in which a virulent strain of virus is also inoculated into the lumbar segment of the cord were associated with the prevention of further spread within the CNS even though antibody was not administered until 24 to 48 hours after the intraspinal injection of virus This suggests the possibility that the development of high concentrations of antibody, even after CNS invasion by virus, could result in limitation of virus spread and could conceivably, in some instances, convert a potentially destructive CNS invasion into one that could be self-reversing and without crippling effect Thus, it is possible to imagine that the degree of immunologic hyper-reactivity that might persist after vaccination, if operative after onset of infection, could either prevent or ameliorate the effects of CNS invasion, depending upon the time lapse between virus invasion and rise in concentration of antibody

The delicate time-balance between the effect of the invasive properties of the virus and the immunologic defense of the host could be the critical factor that determines whether or not paralysis will occur, and it is conceivable that this mechanism could operate even without a prior antigenic stimulus However, the hypothesis proposed is that prior immunologic stimulation places the host at an advantage, more so if antibody is present in the serum, or at an advantage that is in proportion to the degree to which antibody can be produced before extensive and irreversible effects have occurred in the CNS This concept, although plausible, is still hypothetical and provides a convenient way of regarding the balance between pathogenic and immunogenic forces as these could influence the encounter between virus and host It also provides a way of regarding the role of immunization and of the way in which the important quantitative and qualitative factors must be manipulated to produce a desired effect

Resistance to Infection vs Resistance to Paralysis

There are many circumstances under which infection can occur which does not result in paralysis (1) Passively transferred antibody in the infant suppresses paralysis but does not inhibit infection (2) The resistance to paralysis induced by a cross-related heterotypic infection is not accompanied by resistance to infection (Salk, 1955a, 1956a) (3) It has been shown that primary vaccination is able to induce resistance to paralysis, but this does not appear to prevent the establishment of infection resulting either from feeding of attenuated viruses (Sabin, 1957) or that naturally acquired (Gelfand et al, 1956)

However, the consequences of natural infection, or of infection induced artificially by feeding attenuated virus, does result in resistance to reinfection in a high proportion of persons The fact that such resistance does not necessarily exist in all who had previously been infected suggests that there is a qualitative component to the immune mechanism that could conceivably be simulated by an immunizing procedure that does not necessitate the process of infection For example, Howe (1955) has shown that high titers of antibody, resulting from repeated inoculations of chimpanzees with formalin-treated virus, is accompanied by limitation in viral excretion after feeding live-virus, or to re-

all 3 types; of the remaining 44, all reacted with antibody formation to a level of 1:64 or greater for type II, and lower levels of antibody for types I and III were present in all but one instance It is clear from these observations that all of the children involved were capable of forming antibody if stimulated by a sufficient concentration of antigen. The lesser response to types I and III reflect, in these instances, lesser antigenic potencies of the types I and III components of certain of the lots of vaccine involved in this study

In the course of extensive serologic studies involving about 15,000 persons, mostly children but including some adults, rare instances have been observed in which an individual appears to be poorly responsive, or relatively refractory, to 1 of the 3 antigenic components of the vaccines employed The reasons for these unusual effects are not clear, but the facts are illustrated in Figure 83 Here it may be seen that a child who responded well to types I and II, but not to type III, reacted differently from another individual who reacted poorly to type I but appeared to react in the expected fashion to the type III component to which the child was nonreactive The same lots of vaccine were not used throughout the course for both individuals, but there was sufficient similarity for this comparison These extreme examples may reflect either an inborn or an acquired refractoriness to certain antigens, possibly based on the same mechanism as similar examples in other antigen systems

IMMUNOLOGIC FACTORS INVOLVED IN THE IMMUNITY MECHANISM

From the nature of the pathogenesis of the paralytic disease, it is readily understandable that antibody in the serum would be effective in protecting the central nervous system from invasion by virus and in this way prevent paralysis However, there are some individuals in whom paralysis does not occur even though specific serum antibody was not present before exposure to infection In such instances it might be said that the virus may have been essentially noninvasive However, certain observations provide a basis for doubt that this is the full explanation. The first observation to arrest attention is the greater frequency with which type I paralytic polio occurs in persons who have had an earlier type III infection, as compared with individuals who have had a prior type II infection (Salk, 1955a; 1956a; Hammon, and Ludwig, 1957). The mechanism for protection against paralysis could be the result of the presence of type I antigen in type II viruses (Melnick, 1955) and due to the effect of nondemonstrable type I antibody in the serum, as sometimes does appear in convalescence from type II infections in man (Sabin, 1952) However, the fact that type I antibody activity may not be readily demonstrable makes it necessary to examine whether or not such activity is actually present and, therefore, whether the foregoing explanation is sufficient. Perhaps other factors may be operative.

Further pursuit of this question is possible because of the observations of the difference in type I antibody response in vaccinated persons who have had a prior type II infection as compared with those who have had a prior type III infection (Salk, 1955a). Figure ■ illustrates this difference and suggests the existence of significant type I immunologic hyper-reactivity in those who have had a prior type II infection, in comparison with those who have had a prior type III infection The question then arises as to whether or not a relationship may exist between the protective effect against type I paralysis among those who have had a prior type II infection and their heightened reactivity to type I antigen

The phenomenon of immunologic hyper-reactivity, or the booster phenomenon in immunology, is associated not only with a greatly increased production of antibody but also with earlier appearance of greater concentrations of antibody in the serum Regardless of whether the hyper-reactive mechanism results in the more rapid appearance of antibody or merely a greater production, there is the reasonable question as to whether or not heightened immunologic reactivity could play a role in prevention of paralysis, under circumstances where the incubation period before paralysis is such as to permit antibody to be effective in reducing the probability of paralysis. From studies on the pathogenesis

formation consistently exerted a more complete effect, and antigenically poor lots were demonstrated to have been relatively ineffective in preventing paralysis by the type for which there was antigenic deficiency Francis et al (1957) concluded that, "These studies leave little doubt that the effectiveness of the vaccines in the Field Trial of 1954 was closely associated with, perhaps entirely dependent upon, the ability of the lots of vaccine used to produce discernible type-specific antibody rise in children who previously had no discernible type-specific antibody" From data on type I vaccine effectiveness, it appeared that practically all type I paralytic cases in vaccinated children occurred in groups given lots of vaccine in which antigenic effectiveness was computed to be less than 70 per cent A vaccine that was 70 per cent effective antigenically was one that induced the formation of antibody levels (of 1 4 or greater, when tested against 100 ID_{50} of virus) in 70 per cent of children who previously had no discernible type-specific antibody. Thus, it was observed that vaccines that exceeded 70 per cent effectiveness in inducing antibody formation approached 100 per cent effectiveness in resistance to paralysis

In the Francis et al report (1957), detailed data are presented on questions of reactions and of safety, as well as the question of provocation of paralysis by inoculation There was no evidence of unsafe vaccine, in the sense of infection induced by the vaccine, nor evidence of provocation The administration of vaccine seemed to have been essentially free of associated side-reactions

Experience Subsequent to Field Trial

Among the first lots of vaccine released for general use in the United States, in April, 1955, there were several, prepared by one manufacturer, that were associated with the development of paralytic poliomyelitis in inoculated children (Langmuir et al, 1956) In

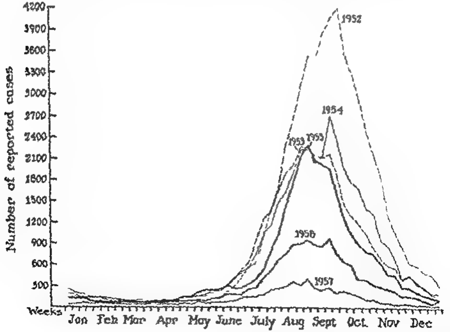

FIG 84 Weekly United States Poliomyelitis Incidence 1952-1957 Data provided by National Office Vital Statistics and chart reproduced with permission of Poliomyelitis Surveillance Unit, Communicable Disease Center, United States Public Health Service Data are total reported cases including paralytic and nonparalytic.

sistance to the establishment of the carrier state.

Whether or not, and to what degree, vaccination of man with a killed-virus vaccine will affect the rate of poliovirus infection, as distinct from the paralytic rate, after high concentrations of antibody are induced, will require further study. If experience in the course of widespread application indicates a reduction in poliomyelitis out of proportion to the number of individuals injected and if there is a reduction in nonparalytic, as well as in paralytic cases, and if there is no evidence that vaccination affects the fecal carrier state, then it becomes necessary to consider the possibility that the fecal source of virus may be less important in the spread of this disease and, as suggested by Rivers, that some other source, such as the pharynx, may be more important. Vaccination might possibly have an effect upon the pharyngeal source of virus dissemination while influencing to a lesser degree the fecal source. In this regard, it is known that virus disappears from the pharynx within approximately 1 week after onset of symptoms, but that virus can still be found in feces for weeks and sometimes months later. Fecal virus persists in spite of the presence of good concentrations of serum antibody; the latter appears to remain at a fixed level or to decline slightly in spite of the presence of virus in the intestine. The nature of this state is not clearly understood.

It is generally believed that exposure of contacts during the latter part of the incubation period, or within 7 days of onset of symptoms, is the kind that results in spread of infection, with less likelihood of ready spread resulting from later contacts, when the only source of virus from the infected or convalescent carrier is bowel excreta. The latter source of infection may be of greater importance under circumstances of poor community hygiene, or contamination of food and water, or by improper sewage disposal.

Field Trial of 1954

In a remarkable study, probably never again to be repeated for any disease, Francis (Francis et al., 1957) directed a field evaluation of vaccination against poliomyelitis. The details of this study, to the report of which the reader is referred, are too numerous to present and will be indicated here only in essence.

Two types of observations were made: one in which volunteer children in the first 3 grades of school were randomly divided into alternate individuals to whom either vaccine or a placebo injection was administered. In other areas, vaccine was given to volunteer children in the second grade and comparisons were made with nonvolunteer children, in the same grade, who were not vaccinated and with nonvaccinated but recorded volunteer children in the first and the third grades. A total of 1,829,916 individuals were under observation during the period of study. In the strictly controlled placebo study 200,745 children received 3 doses of vaccine, and 201,229 received 3 doses of the placebo injection. In the observed study 221,998 children in the second grade received 3 doses of vaccine. The 3 doses of vaccine were given within an interval of 5 weeks, the first 2 doses 1 week apart and the second 4 weeks later.

Under the circumstances of primary vaccination, without the added advantage of the secondary stimulus, for which a longer interval is required, and the added circumstance that the preservative used in the vaccine had caused a definite but variable deterioration of the type I component of the vaccine, and deterioration to a lesser extent of the type II and type III components, there was demonstrated an over-all reduction of 70 per cent in paralytic disease in the Placebo Control Study and 62 per cent in the Observed Control Study. Analysis only of cases in which laboratory confirmation of diagnosis could be established by virus isolation recorded the degree of effectiveness in the respective studies as 82 per cent and 76 per cent. The virus positive cases in the Placebo Study revealed the following degrees of effectiveness in preventing paralysis for the respective types. I, 71 per cent, II, 100 per cent, and III, 95 per cent. The same distinctions in the Observed Study revealed 71 per cent for type I; 75 per cent for types II and III.

It was clear that the effectiveness of the vaccine employed was in proportion to the demonstrated antigenic potency of the particular lot—vaccines that induced antibody

addition, family associates, and other contacts of children given vaccine from the implicated lots, developed paralytic poliomyelitis Further use of vaccine prepared by this manufacturer was discontinued, and after review and reconsideration, the general use of vaccine prepared by other manufacturers was continued Although supply was limited, use of vaccine was sufficiently extensive to reveal a distinctly protective effect, even among individuals given a single dose of vaccine (Langmuir et al., 1956). Further use of vaccine in 1956 and 1957 seems to have been associated with an over-all reduction in incidence of disease in the United States (Langmuir, 1957) beyond that accountable for merely on the basis of the number of individuals inoculated, in whom the incidence of disease is lower than in the nonvaccinated Some have regarded this as an indication of vaccine effect upon the reservoir of infection, although it is cautioned that this may merely represent normal variation in a fluctuating incidence The experience in the United States over the years 1952-1957 is shown in Figure 84.

In a number of smaller countries in which the incidence of paralytic poliomyelitis is generally restricted to the youngest age group, and where populations are relatively small, the use of vaccine appears to have been associated with a very sharp reduction in occurrence of this disease

SUMMARY OF PRACTICAL IMPLICATIONS

On the basis of current knowledge and experience, the following suggestions may be made for use of vaccine for the control of paralytic poliomyelitis·

The vaccine employed should be of such potency that when 2 doses are administered, by whatever route, within an interval of approximately 1 month, the formation of neutralizing antibody (neutralization of 100 ID_{50} by approximately 0 1 ml of serum) is elicited in at least 75 per cent of children who have had no prior contact with poliovirus infection

A third dose of vaccine should be administered 6 to 7 months or longer thereafter. Satisfactory responses have been elicited at shorter intervals of 3 to 4 months when tested because the interval available before the ensuing poliomyelitis season was short; the longer interval provides greater opportunity for development of the hyper-reactive state.

In countries where paralytic poliomyelitis does occur in adults, it would be desirable to immunize mothers, preferably before conception, or early in pregnancy In this way, the relatively more exposed young mother who is also more susceptible in pregnancy, is protected; and the fetus is also protected if the mother might otherwise experience an infection with viremia.

The infant should be immunized before maternal antibody is lost, i e, between 2 and 6 months of age (Thrupp, 1958). It is probable that the means for immunization against poliomyelitis and against diphtheria, tetanus and pertussis may soon be combined or, at least, be practiced simultaneously.

Further observations will be required to determine the duration of protection and the need for further inoculations It is clear that antibody is not evanescent and that immunologic hyper-reactivity persists for a considerable period and possibly for life after effective immunization has once been induced

In countries in which the age distribution of paralytic poliomyelitis is low, the disease can be controlled by immunization of the affected age groups first and then, as supplies of vaccine are available, to extend the use of vaccine to those in older age groups, to protect those few who may have escaped natural immunization in their earlier years

The Coxsackie Virus Group

INTRODUCTION

The Coxsackie viruses comprise 2 groups of small agents having similar physical and biologic properties. Their most striking biologic property is pathogenicity for newborn mice and hamsters and the nature of the lesions which permit their identification and assignment to Group A or B. Throughout the world they are common enteric infections in man. Their seasonal and geographic distribution is not unlike that of the polioviruses. They cause a variety of illnesses, including several clinically distinct ones.

HISTORY

The first strains of what are now known as the Coxsackie viruses were isolated from the feces of 2 boys suffering from paralytic poliomyelitis (Dalldorf and Sickles, 1948). They were the first evidence of the existence of the large and growing number of hitherto unsuspected enteric agents currently subdivided into Coxsackie and ECHO viruses. The original interest in the Coxsackie viruses was related to their association with and simi- [illegible]

became known as the Group-B viruses (Dalldorf, 1950) were isolated, and it was suggested that the latter might induce aseptic meningitis and be responsible for epidemic myalgia or Bornholm disease (Curnen et al., 1949). This was confirmed the following year (Weller et al., 1950; Kilbourne, 1950). In 1951, evidence was secured connecting certain Group-A viruses with herpangina (Huebner et al., 1951) and 2 years later a Group-B [illegible]

demonstration that strains representing 2 Group-A types are capable of causing poliomyelitislike lesions in monkeys (Dalldorf, 1957a) and the claim that one of these was [illegible]

since too little was known of the pathogenesis of human infections to justify a descriptive term (Dalldorf, 1949a). Coxsackie is the name of the village in which the outbreak occurred from which the original isolations were made.

CLINICAL PICTURE

The incubation period of infection by viruses of the Coxsackie group appears to range

from 1 to 14 days with a mean between 3 and 5 (Curnen, 1950, Findlay and Howard, 1950; Huebner et al, 1951, Warin et al., 1953)

The manifestations of infection in man by individual Coxsackie viruses are not uniform, but the association of some of these viruses with particular disease entities has been recognized to represent a causal relationship Classification of Coxsackie viruses into Groups A and B, based on the character and the distribution of lesions experimentally induced in suckling mice, has useful application in considering the relations of these agents to human disease. Five antigenically distinct viral "types" of Group B and 23 of Group A have been identified All of the Group-B viruses and approximately half in the Group-A category have been shown to cause clinically recognizable disease. Information concerning the clinical significance of other Group-A types is still equivocal or lacking Meanwhile, there is no assurance that the growing list of Coxsackie viruses is yet complete. Moreover, recent recognition that certain viruses have properties common to both the Coxsackie and other viral groups has made classification of these agents and delineation of their relation to associated disease more, rather than less, complex (Dalldorf, 1957b, Melnick, 1957b) At present the clinical picture of infection by Coxsackie viruses might be likened to a painting in which important features are clearly delineated but many details remain indistinct. Therefore, an attempt at this time to present a comprehensive description of infection by Coxsackie viruses would still be premature Nevertheless, it is possible to point out certain diseases which are caused by particular Coxsackie viruses and to indicate others in which the etiologic relation of virus to disease is suggested but less firmly established.

Aseptic Meningitis

It has become increasingly evident that Coxsackie viruses of Group B, Types 1 to 5 not only are capable of causing meningitis but periodically and seasonally in summer and fall are probably responsible for a considerable proportion of cases assigned a clinical diagnosis of aseptic meningitis or "nonparalytic" poliomyelitis Initially, the evidence for an etiologic relationship was indirect, based on epidemiologic and clinical findings, recovery of virus from feces and pharyngeal swabbings of patients, detection of serologic response to infection with the homologous strain, and failure to demonstrate evidence of infection with poliomyelitis, mumps, or other virus (Curnen et al, 1949; Melnick et al., 1950; Gard and Johnsson, 1952, Rhodes et al, 1953; Stanley et al., 1953; Gard, 1954; Johnsson, 1954, 1955a, b, c, d; Wilkins et al, 1955, Bayer and Gear, 1955, Syverton et al., 1957).

Possibly of some additional value as evidence is the accumulating experience that during interepidemic periods these agents are infrequently found in the feces of children who are healthy or afflicted with other common diseases (Cole et al., 1951; Ramos-Alvarez and Sabin, 1954, Parrott et al, 1955, Johnsson, 1955c; Rhodes and Beale, 1957) and have been encountered only rarely in the feces of patients with paralysis (Kirby and Evans, 1955; Dalldorf, 1955; Johnsson, 1955c, Rhodes and Beale, 1957).

In recent years more direct and convincing evidence that Group-B strains can cause meningitis has been afforded by the recovery of virus from the spinal fluid of patients during the acute stage of illness. This has now been accomplished with strains of all 5 Group-B types: Type 1 (Girardi et al, 1957); Type 2 (Hummeler et al, 1954; Rhodes and Beale, 1957; Melnick, 1957); Type 3 (Gabinus et al, 1952, Gard, 1954, Girardi et al, 1957, Hummeler, 1957; McLean et al, 1957), Type 4 (Gard, 1954, Hummeler, 1957, Rhodes and Beale, 1957), and Type 5 (Curnen, 1957).

The clinical findings in patients with meningitis attributable to a Coxsackie-B virus provide no distinctive indication of the virus type responsible. Meningitis may occur independently or in association with pleurodynia The latter is more common in older children and adults and is possibly more likely in patients infected with B-1 and B-3 viruses (Johnsson, 1954; Rivadeneira et al, 1957). The onset may be sudden or gradual In approximately half of the cases illness is initiated by a prodromal phase of 2 to 6 days and is occasionally interrupted by a brief asymptomatic period. It is noteworthy that

viremia with Coxsackie virus B-2 was demonstrated recently with serum obtained from a patient with prodromal symptoms 5 days prior to the onset of clinical meningitis (Shelokov and Habel, 1957). Malaise, loss of appetite, nausea and abdominal pain are common early Fever may be present at the onset or develop subsequently in association with the appearance of headache, drowsiness, vomiting, stiffness or discomfort in the neck and the back, and sometimes focal or generalized myalgia The elevation of temperature ranges only occasionally above 40° C and lasts from 3 to 10 days with a mean of about 4 to 5 days On physical examination patients do not appear particularly ill and reveal few objective indications of disease. Hyperemia of the pharynx may be present during the acute stages Resistance of the neck or the back to anterior flexion is usually demonstrable but not extreme and rarely persists for more than a few days longer than the fever The Kernig and the Brudzinski signs can usually be elicited The deep and superficial reflexes remain normal Evidence of muscular weakness is equivocal or lacking Tremor, persistent muscular stiffness and skin rash are not characteristic findings The total and differential white blood cell counts are usually normal or only slightly elevated Leukopenia is not a feature of the disease Examination of the cerebrospinal fluid early in the acute phase of illness reveals an increase in the number of leukocytes which in most instances does not exceed 500 In patients infected with B-5 virus the total counts may range as high as 2,000 (Curnen, 1957) In the differential count mononuclear cells outnumber the polymorphonuclear cells, the latter, however, may initially account for 10 to 50 per cent of the total The protein content of the fluid is normal or only slightly elevated The amount of sugar present is also normal Except in very young infants with associated myocarditis, the course of illness is characteristically uncomplicated and terminates in complete recovery, although in adults fatigue and irritability may persist for as long as 2 months

It is now apparent that in addition to the Group-B strains, a number of Group-A viruses may also cause aseptic meningitis Russian workers have reported the recovery from the stools of paralyzed children of a so-called "Type 4 poliovirus" which experimentally induced paralysis and lesions in monkeys typical of poliomyelitis (Chumakov et al, 1956) Russian strains of this agent have been identified recently as Coxsackie virus A-7, and other strains recovered in this country have been

1957) There is some evidence that Coxsackie A-7 virus may also cause aseptic meningitis in man (Johnsson, 1955c, Johnsson et al, 1957, Habel et al, 1957, Kilbourne and Goldfield, 1956). In a "controlled" study Coxsackie A-9 strains were recovered 5 times more frequently in patients with aseptic meningitis than was expected (Habel et al, 1957), and in 2 cases the A-9 virus has been recovered from spinal fluid (Melnick, 1957) In South Africa, Group-A viruses of unspecified type were recovered from 7 patients with aseptic meningitis, in 3 instances from the spinal fluid (Gear et al., 1956).

A "new" Group-A virus not neutralized by antisera for Types 1 to 19 was encountered frequently in scattered outbreaks of aseptic meningitis which occurred in Italy during the summer of 1955 The virus was reported to have been recovered from spinal fluid in 53 instances. Respiratory or gastro-intestinal prodromata frequently preceded the meningeal syndrome Pleocytosis of the cerebrospinal fluid was unusual, total counts up to 6,000 were recorded (Archetti et al, 1957)

During the summer and the fall of 1956, outbreaks of aseptic meningitis frequently associated with a maculopapular rash were prevalent in Europe (Tyrrell and Snell, 1956, Rotem, 1957, Garnett et al, 1957, Boissard et al, 1957, McLean and Melnick, 1957, Tyrrell et al, 1957, Lennartz et al., 1957, Hennessen, 1956, Nihoul and Quersin-Thiry, 1957, Archetti et al, 1957, Rita et al, 1956, Baumann et al, 1957). The disease appears to be attributable to a virus which was recovered in a high proportion of cases from the feces and frequently also from spinal fluid This agent, which has properties of a Group-A Coxsackie virus, is neutralized by antisera against ECHO virus Type 9 A proposal has been made that this agent should properly be

classified as a new member of the Coxsackie-A group of viruses (Quersin-Thiry et al , 1957).

EPIDEMIC MYALGIA OR PLEURODYNIA (BORNHOLM DISEASE)

The first published descriptions of this disease came from Norway (Daae, 1872; Homann, 1872), although apparently outbreaks had been observed in 1856 and 1863 in Iceland (Finsen, 1874) Accounts of the same or similar disease called by a variety of names have since been recorded in different parts of the world. The monograph by Sylvest (1934) represents a classic description of this malady and has stimulated greater attention to it During the past 10 years Group-B Coxsackie viruses have been found in association with pleurodynia under circumstances which strongly indicate an etiologic relationship In patients infected with a single B-1 type of virus initially designated Conn-5, whose illnesses resembled pleurodynia (Curnen et al , 1949, Curnen, 1950, Weller et al , 1950, Kilbourne, 1950, Shaw et al , 1950), the clinical features corresponded generally to those encountered in the past (Sylvest, 1934) and in a typical outbreak which occurred in 1947 in Massachusetts (Finn et al , 1949) Cases of pleurodynia associated with the B-1 virus were also observed in 1952 in Japan (Yokota, 1955) and during 1956 in various areas of Great Britain (Medical Officer, Editorial, 1957). Strains of Coxsackie virus B-3 have been recovered from patients in several widely separate epidemics of pleurodynia (Gabinus et al., 1952, Lazarus et al , 1952, Huebner et al , 1953, Warin et al., 1953, Disney et al , 1953; Johnsson, 1955d; Derrick et al , 1956) The associations of pleurodynia with B-4 Coxsackie virus has been reported from South Africa (Patz et al , 1953; Wilkins et al., 1955) A laboratory worker accidentally infected with B-2 virus had clinical manifestations of both pleurodynia and aseptic meningitis (Curnen, 1950, 1952, Shaw et al., 1950). In numerous other studies of pleurodynia strains of Group-B virus have been recovered but not identified further. In outbreaks of aseptic meningitis associated with B-5 infection pleurodynia has not been noted There is no convincing evidence that Group-A Coxsackie viruses can cause this syndrome.

Clinical manifestations encountered in patients with pleurodynia associated with infection by a Group-B Coxsackie virus correspond to those described by Sylvest and more recently summarized in the report of a B-3 outbreak in Great Britain (Warin et al , 1953). Fever and pain, which are almost invariably present together, are usually abrupt in onset; occasionally, they may be preceded for several hours or days by malaise, anorexia and other vague prodromal symptoms The pain is most commonly thoracic, especially in adults, and is often accompanied by headache Pain in the chest, located on either side or substernally, may be excruciating but varies considerably in character and severity It is intensified by movement and may last from 2 days to almost 2 weeks Abdominal pain occurs in approximately half the cases, more commonly in children, and may be present in the absence of thoracic pain. This is frequently periumbilical or located on the right side more often than on the left Aches in the trunk or the extremities are sometimes noticed Stiffness of the neck or the back is an occasional complaint Nausea and vomiting are infrequent Cutaneous hyperesthesia is unusual. The elevation and the duration of fever correspond to those noted in patients with aseptic meningitis The course of acute illness is sometimes diphasic Tenderness which may be present over the site of pain, particularly in the abdomen, appears to be superficial suggesting localization in the muscular wall rather than in the viscera. In some instances swelling of a muscle is noted. In occasional patients with stiffness of the neck or the back the complaint is manifested by resistance to anterior flexion. The occurrence of associated meningitis in some cases of pleurodynia was recognized in the past (Lindberg, 1936; Gsell, 1949) but has now been firmly established in typical cases attributable to Group-B Coxsackie viruses. In one series of 262 cases of pleurodynia with B-3 infection the incidence of proved meningeal involvement was 2.6 per cent (Warin et al , 1953) The meningeal disease and the characteristics of the cerebrospinal fluid in these circumstances correspond to those seen in uncomplicated meningitis attributable to the same virus In pleurodynia the blood picture, urinalysis and other clini-

cal laboratory determinations are usually within the normal range. Orchitis appears sometimes as a complication of pleurodynia (Sylvest, 1934; Warin et al, 1953) The course of the disease is usually self-limited and terminates in complete recovery

Myocarditis of the Newborn

Recent reports indicate that Group-B Coxsackie viruses may induce intra-uterine or neonatal infection manifested in newborn infants by clinical and pathologic evidence of acute myocarditis

In 1952 during an epidemic of Bornholm disease in Johannesburg, South Africa, 10 babies with myocarditis were observed (Javett et al, 1956). Of these 6 developed circulatory collapse and died Strains of Coxsackie virus B-3 were recovered from the feces of 2 surviving infants Lesions resembling those caused by a Group-B Coxsackie virus were seen in suckling mice injected with suspensions of brain prepared from each of 2 babies who died

Of 3 infants with myocarditis observed during 1954 in a maternity home in Southern Rhodesia 1 died and 2 recovered (Montgomery et al, 1955) Coxsackie virus B-4 was found in specimens of feces from the baby who died and from 1 of the survivors Strains of this virus were also recovered from patients with Bornholm disease and meningo-encephalitis which were prevalent at the same time

In 1955 during an epidemic of "summer grippe" among adults in Amsterdam, 4 fatal cases of myocarditis in newborn infants were studied (van Creveld and de Jager, 1956, Verlinde et al, 1956) The clinical diagnosis of myocarditis was confirmed by electrocardiographic changes during life and the demonstration of acute interstitial myocarditis at autopsy Strains of B-4 Coxsackie virus were recovered from the heart muscle of each patient and in 1 instance from the brain

Two similar cases were encountered in Boston (Kibrick and Benirschke, 1956) Coxsackie virus B-3 was detected in a specimen of thoracic spinal cord from 1 infant delivered by cesarean section who died on the 7th day of life presumably as the result of infection contracted in utero. Recovery of a B-4 Coxsackie virus from another infant with fatal myocarditis was also mentioned

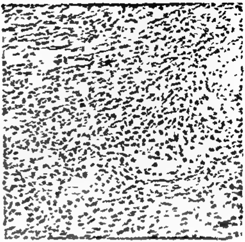

Fig 85 Myocarditis in a newborn infant caused by a B-4 Coxsackie virus (Creveld, S van, and de Jager, H, 1956, Myocarditis in newborns, caused by Coxsackie virus, clinical and pathological data, Ann Paediat *187*, 100-112)

The disease in newborn infants appears with sudden onset, in most instances within the first 8 or 9 days of life, sometimes a few hours or days after a brief episode of diarrhea and anorexia. Lethargy, grayish pallor and mild icterus are common features Tachycardia dyspnea and cyanosis, which may be present early in the course, indicate cardiac and respiratory embarrassment Either depression of body temperature or fever with elevations to 40° C may be encountered Cardiomegaly and hepatomegaly are characteristic features, the spleen may also be palpable Electrocardiograms show changes characteristic of myocarditis. Examination of the cerebrospinal fluid may reveal xanthochromic fluid, leukocytic pleocytosis and increased protein content.

In some cases the clinical course is biphasic, it may be rapidly fatal, even within an hour of apparent onset, or progress to complete recovery over a period of a week or longer Recovery of virus from the brain as well as from cardiac muscle in some cases, together with histologic evidence of lesions in brain and liver, indicate that myocarditis in the newborn is probably a feature of more generalized systemic disease comparable with that

classified as a new member of the Coxsackie-A group of viruses (Quersin-Thiry et al., 1957).

Epidemic Myalgia or Pleurodynia (Bornholm Disease)

The first published descriptions of this disease came from Norway (Daae, 1872; Homann, 1872), although apparently outbreaks had been observed in 1856 and 1863 in Iceland (Finsen, 1874). Accounts of the same or similar disease called by a variety of names have since been recorded in different parts of the world. The monograph by Sylvest (1934) represents a classic description of this malady and has stimulated greater attention to it During the past 10 years Group-B Coxsackie viruses have been found in association with pleurodynia under circumstances which strongly indicate an etiologic relationship. In patients infected with a single B-1 type of virus initially designated Conn-5, whose illnesses resembled pleurodynia (Curnen et al, 1949; Curnen, 1950, Weller et al., 1950; Kilbourne, 1950, Shaw et al, 1950), the clinical features corresponded generally to those encountered in the past (Sylvest, 1934) and in a typical outbreak which occurred in 1947 in Massachusetts (Finn et al, 1949) Cases of pleurodynia associated with the B-1 virus were also observed in 1952 in Japan (Yokota, 1955) and during 1956 in various areas of Great Britain (Medical Officer, Editorial, 1957). Strains of Coxsackie virus B-3 have been recovered from patients in several widely separate epidemics of pleurodynia (Gabinus et al, 1952, Lazarus et al., 1952, Huebner et al, 1953, Warin et al., 1953; Disney et al, 1953, Johnsson, 1955d, Derrick et al, 1956) The associations of pleurodynia with B-4 Coxsackie virus has been reported from South Africa (Patz et al., 1953, Wilkins et al, 1955) A laboratory worker accidentally infected with B-2 virus had clinical manifestations of both pleurodynia and aseptic meningitis (Curnen, 1950, 1952, Shaw et al, 1950) In numerous other studies of pleurodynia strains of Group-B virus have been recovered but not identified further. In outbreaks of aseptic meningitis associated with B-5 infection pleurodynia has not been noted. There is no convincing evidence that Group-A Coxsackie viruses can cause this syndrome.

Clinical manifestations encountered in patients with pleurodynia associated with infection by a Group-B Coxsackie virus correspond to those described by Sylvest and more recently summarized in the report of a B-3 outbreak in Great Britain (Warin et al, 1953). Fever and pain, which are almost invariably present together, are usually abrupt in onset; occasionally, they may be preceded for several hours or days by malaise, anorexia and other vague prodromal symptoms The pain is most commonly thoracic, especially in adults, and is often accompanied by headache Pain in the chest, located on either side or substernally, may be excruciating but varies considerably in character and severity It is intensified by movement and may last from 2 days to almost 2 weeks Abdominal pain occurs in approximately half the cases, more commonly in children, and may be present in the absence of thoracic pain This is frequently periumbilical or located on the right side more often than on the left. Aches in the trunk or the extremities are sometimes noticed Stiffness of the neck or the back is an occasional complaint. Nausea and vomiting are infrequent. Cutaneous hyperesthesia is unusual. The elevation and the duration of fever correspond to those noted in patients with aseptic meningitis. The course of acute illness is sometimes diphasic. Tenderness which may be present over the site of pain, particularly in the abdomen, appears to be superficial suggesting localization in the muscular wall rather than in the viscera In some instances swelling of a muscle is noted In occasional patients with stiffness of the neck or the back the complaint is manifested by resistance to anterior flexion. The occurrence of associated meningitis in some cases of pleurodynia was recognized in the past (Lindberg, 1936; Gsell, 1949) but has now been firmly established in typical cases attributable to Group-B Coxsackie viruses. In one series of 262 cases of pleurodynia with B-3 infection the incidence of proved meningeal involvement was 2 6 per cent (Warin et al, 1953). The meningeal disease and the characteristics of the cerebrospinal fluid in these circumstances correspond to those seen in uncomplicated meningitis attributable to the same virus. In pleurodynia the blood picture, urinalysis and other clini-

tion was demonstrated in a number of patients by Maryssael (1952) who used various electrical stimuli to analyze the nature of the lesion The early use of biopsy in the study of individuals infected with Coxsackie viruses (Dalldorf, 1949c) was abandoned to avoid danger to patients who might be infected with poliovirus

EXPERIMENTAL INFECTION, HOST RANGE

The experimental disease has been studied most thoroughly in mice, although similar responses occur in other animals, for example, hamsters, suckling ferrets and meriones The lesions in susceptible animals are the criteria used in identifying Coxsackie viruses and classifying them into Groups A and B This has proved to be reliable (Johnsson and Lundmark, 1955, Paola et al, 1952-53, Dalldorf, 1958) because even though the individual lesions are not strictly pathognomonic (see below) the pattern is distinctive There is no record of an individual Coxsackie virus of established type that causes lesions incompatible with the group to which it belongs The only confusion thus far has arisen from inocula that contained a mixture of viruses The combination of Group-A and -B lesions in an individual mouse should always suggest a search for a second virus

The pattern of the anatomic response varies with the route of inoculation Cerebral lesions, for example, are more frequent following Group-B infections if the animals have been injected intracerebrally (Gifford and Dalldorf, 1951) One lesion may predominate due to type and strain differences These properties may change with further adaptation, and some are known to depend on the tissue used for inoculation The pancreatotropism of certain Group-B viruses was lost following prolonged brain to brain transfer and intensified by the use of visceral and pancreatic suspensions (Dalldorf and Gifford, 1952) None of these differences seems to have seriously complicated diagnosis by histologic means The value of the distinction between the 2 groups rests largely on their significance in human disease Thus Bornholm disease and myocarditis neonatorum have only been associated with Group-B viruses, herpangina only with Group-A types

FIG 86 Focal necrosis of human muscle associated with a Group A Coxsackie virus infection (Gadeke, R, 1952, Vergleichende morphologische und chemische Muskelbefunde bei Säuglingsmausen und Meerschweinchen nach experimenteller Infektion mit Viren der Coxsackie-A-Gruppe, Klin Wchnschr *30*, 1040-1041)

As might be expected, the signs of disease in infant mice are also distinctive and will usually indicate the group to which the virus belongs

Group A Mice infected with Group-A viruses become helplessly paralyzed after a brief period of weakness Their extremities are leaden and immobile, and death soon follows, possibly from paralysis of the muscles of respiration Lépine et al (1952), who inoculated their mice intraperitoneally, noted herniation of the abdominal wall in many animals of the first 2 passages Presumably, as the strains became better adapted to mice, the local muscle lesion was submerged in the general degeneration of all skeletal muscles, and the hernias were no longer seen Those that survive for a week or more usually have whitish streaks in their muscles that are easily seen once the animal has been skinned Histologic examination of such animals will show a well-nigh universal degeneration or destruction of the striated muscles. The tongue and the heart are spared The most useful diagnostic features are the generalized myositis and the

seen in suckling mice infected with the same virus.

Cardiac complications of infection by Coxsackie viruses in older children and adults have not been reported frequently but may have been overlooked. Coxsackie B-2 virus was recovered from the feces of a 5-year-old boy in Ohio who had acute myocarditis and in whose blood a rising titer of neutralizing antibody against the virus was subsequently detected (McLean et al., 1957) Recently 2 cases of "benign pericarditis" were reported, 1 associated with a B-4 strain (Fletcher and Brennan, 1957) and another with a B-5 strain (Weinstein, 1957). Coxsackie virus B-5 was recovered from the stool of a 30-month-old boy with subacute myocarditis, and an associated increase in neutralizing and complement-fixing antibodies against this agent was detected (Varcasia and Castelli, 1957)

Herpangina

This clinical syndrome (Zahorsky, 1920, 1924), which occurs in the summer season and mainly affects children, has been found to be caused by any one of 6 different Group-A Coxsackie viruses, including Types 2, 4, 5, 6, 8 and 10 (Huebner et al, 1951, Parrott et al, 1951) The clinical and epidemiologic aspects of this disease have been reviewed recently (Parrott, 1957, Parrott and Cramblett, 1957)

The illness is initiated by a relatively abrupt onset of fever which affects 90 per cent of patients, ranges to a maximum of 40.5° C. and lasts from 1 to 4 days with a mean of about 2 days Anorexia and dysphagia are frequent symptoms Most patients over 2 years of age complain of sore throat, and about a third of them are afflicted with vomiting; fewer complain of headache or abdominal pain Convulsions associated with fever occur in about 5 per cent of cases Generalized myalgia is not a feature of the disease. Patients with herpangina do not appear very ill. The pharynx is usually hyperemic. Discrete and characteristic oral lesions may be seen They are commonly located on the anterior pillars of the fauces, less frequently on the palate, the uvula, the tonsils or the tongue and not on the gingival or the buccal mucosa. The early individual lesion appears as a grayish-white papule or vesicle about 1 to 2 mm. in diameter, surrounded by a red areola Within 2 or 3 days the areola becomes more intensely red, the vesicle enlarges and assumes the appearance of a shallow grayish ulcer which is rarely more than 5 mm. in diameter. Vesicles and ulcers may be present concomitantly and are usually evident during a period of 4 to 6 days after the onset of illness They range to 14 in number and average about 5 per patient. However, these lesions are not invariably detected during the disease Among closely associated persons infected by the same virus, typical vesicles or ulcers may be present in some and not in others Diarrhea, cough, rhinitis, otitis media, sinusitis and meningeal irritation are not characteristic features of herpangina The blood leukocyte counts are usually normal but may be somewhat elevated, especially if bacterial infection is also present However, pathogenic bacteria are associated with this syndrome only by coincidence The course of illness is usually benign and uncomplicated except for febrile convulsions in relatively few cases The findings of ulcers typical of herpangina adjacent to the vagina of a 7-year-old girl with the disease and the recovery of A-10 Coxsackie virus from these lesions, the throat and feces has been reported (Mitchell and Dempster, 1955). Recently, the occurrence of acute parotitis complicating herpangina in 4 patients infected by a Group-A Coxsackie virus was also noted (Howlett et al., 1957).

PATHOLOGIC PICTURE

The lesions of herpangina are characteristic, and the occasional localized muscle tumefaction in Bornholm disease may also be considered a distinctive manifestation of Coxsackie virus infection The only anatomic observations of fatal human disease are the myocarditis, at times associated with a degree of encephalitis and in 1 case with inflammatory changes in the spinal cord (Kilbrick and Benirschke, 1956) that have been found in fatal cases of myocarditis in newborn infants (Javett et al, 1956, Montgomery et al, 1955; van Creveld and de Jager, 1956, Verlinde et al, 1956).

Myositis was noted in biopsy samples from 2 human cases by Lépine et al (1952b) and by Vivell et al (1952) in a 6-year-old boy infected with an A-2 virus. Muscle degenera-

tion was demonstrated in a number of patients by Maryssael (1952) who used various electrical stimuli to analyze the nature of the lesion The early use of biopsy in the study of individuals infected with Coxsackie viruses (Dalldorf, 1949c) was abandoned to avoid danger to patients who might be infected with poliovirus

EXPERIMENTAL INFECTION, HOST RANGE

The experimental disease has been studied most thoroughly in mice, although similar responses occur in other animals, for example, hamsters, suckling ferrets and meriones The lesions in susceptible animals are the criteria used in identifying Coxsackie viruses and classifying them into Groups A and B This has proved to be reliable (Johnsson and Lundmark, 1955, Paola et al, 1952-53, Dalldorf, 1958) because even though the individual lesions are not strictly pathognomonic (see below) the pattern is distinctive There is no record of an individual Coxsackie virus of established type that causes lesions incompatible with the group to which it belongs The only confusion thus far has arisen from inocula that contained a mixture of viruses The combination of Group-A and -B lesions in an individual mouse should always suggest a search for a second virus

The pattern of the anatomic response varies with the route of inoculation Cerebral lesions, for example, are more frequent following Group-B infections if the animals have been injected intracerebrally (Gifford and Dalldorf, 1951) One lesion may predominate due to type and strain differences These properties may change with further adaptation, and some are known to depend on the tissue used for inoculation The pancreatotropism of certain Group-B viruses was lost following prolonged brain to brain transfer and intensified by the use of visceral and pancreatic suspensions (Dalldorf and Gifford, 1952) None of these differences seems to have seriously complicated diagnosis by histologic means The value of the distinction between the 2 groups rests largely on their significance in human disease Thus Bornholm disease and myocarditis neonatorum have only been associated with Group-B viruses, herpangina only with Group-A types

FIG 86 Focal necrosis of human muscle associated with a Group A Coxsackie virus infection (Gadeke, R., 1952, Vergleichende morphologische und chemische Muskelbefunde bei Sauglingsmausen und Meerschweinchen nach experimenteller Infektion mit Viren der Coxsackie-A-Gruppe, Klin Wchnschr 30, 1040-1041)

As might be expected, the signs of disease in infant mice are also distinctive and will usually indicate the group to which the virus belongs

Group A Mice infected with Group-A viruses become helplessly paralyzed after a brief period of weakness Their extremities are leaden and immobile, and death soon follows, possibly from paralysis of the muscles of respiration Lépine et al (1952), who inoculated their mice intraperitoneally, noted herniation of the abdominal wall in many animals of the first 2 passages Presumably, as the strains became better adapted to mice, the local muscle lesion was submerged in the general degeneration of all skeletal muscles, and the hernias were no longer seen Those that survive for a week or more usually have whitish streaks in their muscles that are easily seen once the animal has been skinned Histologic examination of such animals will show a well-nigh universal degeneration or destruction of the striated muscles. The tongue and the heart are spared The most useful diagnostic features are the generalized myositis and the

absence of lesions elsewhere Mice infected intramuscularly with Theiler or encephalomyocarditis viruses, for example, also may show Zenker's degeneration of the muscles, but the lesions are limited to the injected extremity (Rustigian and Pappenheimer, 1949), or, if inoculation has been intracerebral, to the muscles of the spinal column In both cases encephalomyelitis also occurs. Group-A Coxsackie viruses affect the entire musculature and do not cause lesions in other organs. These findings and the selective susceptibility of newborn mice have thus far been associated only with Group-A infections.

The process begins within the muscle fibers with loss of definition, followed by hyalin degeneration, fragmentation and clumping (Gifford and Dalldorf, 1951; Godman et al., 1952). Aumonier (1953) found the sequence of early events to be loss of "H" and "Z" lines, followed by loss of "A" and "I" disks. swelling of the myofibrils and, finally, complete loss of internal structure Kausche and Hoffman-Berling (1952) found dense perinuclear zones composed in large part of nucleoprotein within 24 hours of infection The nuclei contained increased amounts of RNA These phenomena disappeared when degeneration became apparent in stained preparations

The Na-K ratio is reversed within 30 hours following infection (Gadeke and Waltenberger, 1952). Sharp losses of creatin and potassium occur (Gifford and Dalldorf, 1949; Gädeke, 1952a) and the excretion of myoglobin may be sufficiently large to cause nephrosis (Gadeke, 1952b). In a subsequent study, Albrecht and Gädeke (1956) illustrated the early histochemical changes Nucleic acid accumulations, in masses of granular or elongated form, were prominent These did not represent an actual increase in nucleic acid content but a mere rearrangement An actual increase in inorganic phosphates was demonstrated and ascribed to the blockade of the normal formation of energy carriers due to the loss of muscle function Several studies of muscle alkaline phosphatase have been reported (Albrecht and Sauthoff, 1954). The succinoxidase, anaerobic glycolysis, and combined glucose-6-phosphate and 6-phosphogluconate activity of muscle is not altered prior to morphologic change The glycolytic activity is lowered on the third day following inoculation, when the mice are paralyzed (Green, 1956)

Mice a few days older may survive, and in them repair replaces degeneration Myoblasts are conspicuous, as well as leukocytes, and

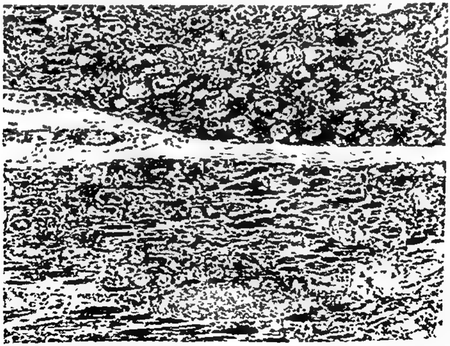

Fig. 87. Hyalin degeneration of striated muscle of an infant mouse infected with a Group A Coxsackie virus. The extreme cellularity is due to repair Extensive lesions of this kind are recognizable grossly.

TABLE 16 EFFECT OF THE ROUTE OF INOCULATION ON THE ISOLATION OF COXSACKIE VIRUSES

(Johnsson, 1955e)

regeneration advances rapidly. Resorption of degenerate muscle proceeds slowly, and evidence of damage may be found weeks later. [illegible]

Mice are susceptible to infection by the intracerebral, the intraperitoneal and the subcutaneous routes and to a much less extent (approximately 10 000 times) by the oral route (Kaplan and Melnick, 1951) Suckling mice 4 to 5 days old are fully susceptible to most Group-A viruses, and adapted strains may infect and paralyze many weanling mice and even older animals if sufficient virus is injected (Gifford and Dalldorf, 1949) Differences in susceptibility associated with route of inoculation are more striking during isolation Johnsson (1955e) has tabulated his experience (Table 16) It has been recommended that groups of mice be inoculated by each of 3 routes—intracerebral (IC), intraperitoneal (IP) and subcutaneous (SC)—and that further passages be made by all 3 routes if necessary (Dalldorf, 1958)

Certain Group-A viruses may induce myositis and paralysis in weaned mice, but serial transfers in such animals have not succeeded (Gifford and Dalldorf, 1949) On the other hand the representative strain of A-14 has been adapted to adult mice and induces in them lesions of the central nervous system similar to those that follow infections with the Lansing and the MEF strains of poliovirus (Dalldorf, 1957a) The adapted virus [illegible]

have been observed to cause similar lesions in adult mice on occasion Ward (1950) has mentioned neuronal necrosis and neuronophagia in the spinal cords of adult mice but did not identify the virus type

The A-14 virus that has been adapted to adult mice causes poliomyelitislike lesions in cynomolgous monkeys following intracerebral inoculation but not overt paralysis The original strains of A-7 also cause such lesions in monkeys (Dalldorf, 1957a), and an A-7 virus isolated by Chumokov et al. (1956) from paralytic cases of poliomyelitis in children frequently causes paralysis in monkeys as well This virus, identified by Chumokov as AB-IV, or poliovirus Type 4, has since been identified as Coxsackie virus A-7 (Johnsson and Lundmark, 1957, Habel and Loomis, 1957, Dalldorf, 1958) Habel and Loomis examined the brains and the spinal cords of 7 monkeys In 4, the lesions could not be distinguished from those caused by poliovirus In the remaining 3, the distribution was somewhat different The A-7 viruses studied thus far have not been pathogenic for adult mice, while the A-14 virus is and, indeed, the monkey and the mouse pathogenicity are associated to a degree

A number of strain and type differences occur among Group-A viruses in addition to those noted A-4, which has at times caused poliomyelitislike lesions in adult mice, is somewhat different in the responses of suckling mice (longer incubation period on primary isolation) and the low incidence of infection (antibodies) in man (Beeman and Huebner, 1952) The titer, in mice, is relatively low, a characteristic of many strains of A-7 and A-9, 11, 13, 15, 16, 17, 18 and 19 as well (Dalldorf, 1957) Only one Group-A type (2) has proved to be readily adapted to growth in embryonated hens' eggs This type includes a single strain that readily causes lesions of the striated muscles of chick embryos that are comparable with those seen in mice Type

FIG 88. Lesions of the spinal cord of an adult mouse following infection with the adult mouse adapted Coxsackie A-14 virus (*Top*) Distribution of the lesion which is largely limited to the anterior horns (*Bottom*) Destruction of motor neurones and their phagocytosis (Dalldorf, G, 1957, Neuropathogenicity of certain Group-A Coxsackie viruses, J. Exper. Med *106*, 69-76)

4 has a lesser ability to grow in chick cells Ten types of Group-A viruses were included in the study (Shaw, 1952) Godenne and Curnen (1952) tested 17 strains, including 16 different antigenic types for growth on the chorio-allantoic membrane. Evidence of multiplication was obtained only with 1 strain (Eastern 10) of Coxsackie Group A, type 10 virus

Cockroaches (*Periplanata americana*) were shown to remain infected with an A-4 Coxsackie virus for 15 days following feeding (Fischer and Syverton, 1951). In a later study it was reported that the gastro-intestinal tracts and salivary glands remained infectious for 20 days (Fischer and Syverton, 1957). The tropical rat mite (*Liponyssus bacoti*) also remained infectious for 2 weeks after feeding on infected mice but rarely transmitted infection to other mice or its progeny (Schwab, Allen and Sulkin, 1952). The virus used was also an A-4 Blowflies and houseflies were both found to harbor Coxsackie viruses for some days following inges-

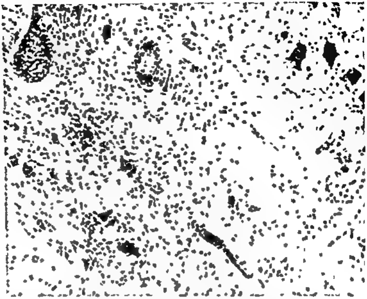

FIG 89 Poliomyelitislike lesion of the spinal cord of a monkey infected with a Coxsackie A-7 virus (Habel, K, and Loomis, L. N, 1957, Coxsackie A-7 virus and the Russian "Poliovirus Type 4," Proc Soc Exper. Biol & Med *95*, 597-605)

tion, but no evidence of virus multiplication was secured (Melnick and Penner, 1952)

A Group-A, Type-4 virus was also found to cause inapparent infections in wild cottontail rabbits and was once isolated from the blood of a naturally infected rabbit trapped in lowlands contaminated with sewage (O'Connor and Morris, 1955) Neutralizing antibodies for A-10 Coxsackie virus were found in nearly half of 40 swine sera and less frequently in rat and cow sera by Pohjanpelto and Vuopio (1956)

Group B In contrast with the inert helplessness of mice infected with Group-A viruses, Group-B mice exhibit tremors, spasticity and spastic paralysis * On dissection, gross evidence of muscle necrosis is uncommon, but changes in the interscapular fat pad may occur that are recognizable with the naked eye, as well as fat necrosis in the region of the pancreas Moreover, the brain may show softening

The degeneration of striated muscles following infection with Group-B viruses is characteristically focal and limited, and the changes in their Na and K content is less marked than following Group-A infections (Carcassi and Gioannini, 1956) The lesions most useful in diagnosis are degeneration of the brown fat (interscapular fat pad), encephalomalacia and, to a lesser degree, hepatitis, myocarditis, and necrosis of the acinar tissues of the pancreas The necrosis of the

ruses Sanz Ibañez, who found no muscle degenertaion in his mice, reported that the peripheral, muscle nerve fibers and motor plates showed nodular (rosary) degeneration (1951). The lesion of the fat pads was for a

The lesion is selective for the brown fat and begins as a degeneration of the cells, usually first on the surface of lobules and progressing to areas of frank necrosis with healing, regeneration and calcium depositions

The cerebral lesion, which occurs in 85 per cent of mice inoculated intracerebrally but in only a fourth of those inoculated intraperitoneally, begins as a patchy dissolution of the cerebral cortex followed by widespread

* A remarkable "zebroid lesion" formed by atro-

liquefaction The lesion is easily recognized grossly The early changes are associated with the cortical blood vessels The necrosis occurs simultaneously in many foci, and encephalomalacia develops very quickly If, because of the age of the mouse, the animal survives, great cysts may be formed in the hemispheres Comparable changes were noted in the spinal cords of some mice by Pappenheimer et al (1950). Levaditi (1951) has discussed the

Lesions of the heart had been noted in many mice infected with the Powers strain (B-4) by Pappenheimer et al (1950). They were less frequently associated with other strains (largely B-1) and occurred in only 3 of 51 mice infected with various field strains of Group-B viruses (Gifford and Dalldorf, 1951). Melnick and Godman (1951) found myocardial necrosis in 3 of 35 4- to 5-day-old mice infected with a B-1 virus and approximately twice as often in animals inoculated the day of birth. The changes are a patchy necrosis followed by fragmentation and hyalin degeneration. The lesion may occur in any part of the myocardium Clusters of eosinophilic granules were found in certain muscle cells (Gifford and Dalldorf, 1951), and these have been the subject of a special investigation (Pappenheimer, 1952). The granules, in-

tensely fuchsinophilic, are from 500 to 600 mμ in diameter, roughly spherical, and were found by Pappenheimer in all the organs in which characteristic Coxsackie virus lesions occur. Pappenheimer referred to these inclusions as "F" granules In his studies, a B-1 virus was used (Conn-5 strain). They have been associated with at least one other

the former the only change was a slowing of the rhythm, but the Group-B mice also showed a lengthened PR interval and in some cases auriculoventricular block

The susceptibility of older mice is sharply increased if they are exposed continuously to cold (4° C) from shortly after inoculation In such animals, Boring et al. (1956) found the infectivity of the tissues increased 10-fold and observed lesions of heart, fat and pancreas It is interesting to note that the effect of cold is quite different from that of cortisone, which was early shown (Kilbourne and Horsfall, 1951) to transform benign into fatal infections in adult mice The effect of cortisone is largely directed to the heart and results in extensive myocardial lesions The cortisone does not influence virus multiplication, which proceeds equally in its absence, but rather acts synergistically (Kilbourne et al, 1956)

The appearance of hepatitis has been unpredictable Hepatitis leading to frank icterus and gastro-intestinal hemorrhage has been associated with some Group-B virus infections but inconstantly The lesions are usually less extensive and consist again of small areas of degeneration and even necrosis of parenchymal cells It is not difficult to distinguish between these lesions and those due to mouse hepato-encephalitis virus, since the latter develops more slowly and is surrounded by a fairly characteristic inflammatory reaction. The occurrence in the liver sinusoids of large refractile cells, possibly derived from the Kupffer cells, noted by Pappenheimer et al (1950), has not attracted the attention of other writers Some of the bodies may have been involuting megakaryocytes

A remarkable necrosis of the acinar epithelium of the mouse pancreas had been noted by Pappenheimer et al. (1950) in animals infected with several Group-B viruses Later, this lesion was studied in greater detail by Pappenheimer et al (1951). The process was remarkable in several respects The destruction was limited to the acinar structures, the islands of Langerhans and ducts being spared, adult mice were susceptible as well as suckling animals. In the older mice, none of the other Group-B lesions occurred The older mice characteristically survived and showed evidence of chronic pancreatic insufficiency, loss of weight, hypoproteinemia and at times anasarca

The discrepancy between these observations and those of Gifford and Dalldorf (1951) were resolved when it was learned that the pancreatotropism of the viruses used was irrevocably lost following prolonged brain-to-brain passage It was present in the same strain on reisolation from the human specimen and could be maintained by passage of visceral suspensions and intensified by pancreas transfers Pancreatic lesions have been rather frequently associated with certain strains and less so with others The method of maintaining the virus and strain differences apparently both play a part

The remarkable events that take place in the pancreas have been studied by means of electronmicrographs (Robertson, 1954). Vacuoles were found in the cytoplasm within 18 hours following infection. They coalesced until the cytoplasm was filled with them. In addition laminated bodies appeared as well as inclusions, sometimes as large as 5 mμ

Howes (1954) successfully titrated several Group-B strains in weaned mice, using pancreatic necrosis as the criterion of infection His method consisted of injecting trypan blue intraperitoneally 4 hours before the mice were killed. The dye made the pancreatic lesions sufficiently conspicuous to read grossly.

Gravid mice become increasingly more susceptible to infection with a pancreatotropic strain of B-1 virus during the last week of pregnancy. A Group-A virus did not have such an effect (Dalldorf and Gifford, 1954).

The effect of whole body radiation on young adult mice infected with the Powers (B-4) Coxsackie virus was an increase in the titer and the persistence of the virus Mortality was little affected (Cheever, 1953).

Coxsackie-B viruses rapidly multiplied in HeLa tumor masses transplanted to the peritoneal cavity of rats and, on serial passage through rat-HeLa tumors, developed increased capacity for destroying solid carcinomata in vivo (Suskind et al, 1957)

Fig. 92. Group B Coxsackie virus infection. (*Top*) An early stage of degeneration of the brown fat. (*Bottom*) Typical appearance of the early changes in the cerebrum. These are the lesions most useful in identifying Group B infections in mice.

liquefaction. The lesion is easily recognized grossly. The early changes are associated with the cortical blood vessels. The necrosis occurs simultaneously in many foci, and encephalomalacia develops very quickly. If, because of the age of the mouse, the animal survives, great cysts may be formed in the hemispheres. Comparable changes were noted in the spinal cords of some mice by Pappenheimer et al. (1950). Levaditi (1951) has discussed the mechanism of this "coelogenesis." Degeneration of motor neurons, including at times neuronophagia, has occasionally been seen in suckling hamsters inoculated intraperitoneally (Gifford and Dalldorf, 1951).

Lesions of the heart had been noted in many mice infected with the Powers strain (B-4) by Pappenheimer et al. (1950). They were less frequently associated with other strains (largely B-1) and occurred in only 3 of 51 mice infected with various field strains of Group-B viruses (Gifford and Dalldorf, 1951). Melnick and Godman (1951) found myocardial necrosis in 3 of 35 4- to 5-day-old mice infected with a B-1 virus and approximately twice as often in animals inoculated the day of birth. The changes are a patchy necrosis followed by fragmentation and hyalin degeneration. The lesion may occur in any part of the myocardium. Clusters of eosinophilic granules were found in certain muscle cells (Gifford and Dalldorf, 1951), and these have been the subject of a special investigation (Pappenheimer, 1952). The granules in-

tensely fuchsinophilic, are from 500 to 600 mμ in diameter, roughly spherical, and were found by Pappenheimer in all the organs in which characteristic Coxsackie virus lesions occur. Pappenheimer referred to these inclusions as "F" granules. In his studies, a B-1 virus was used (Conn-5 strain). They have been associated with at least one other Group-B virus (Dalldorf, unpublished) Their significance has not been established.

Marcolongo et al. (1956) compared newborn mice infected with Group-A and Group-B viruses by means of electrocardiograms. In the former the only change was a slowing of the rhythm, but the Group-B mice also showed a lengthened PR interval and in some cases auriculoventricular block.

The susceptibility of older mice is sharply increased if they are exposed continuously to cold (4° C) from shortly after inoculation. In such animals, Boring et al. (1956) found the infectivity of the tissues increased 10-fold and observed lesions of heart, fat and pancreas It is interesting to note that the effect of cold is quite different from that of cortisone, which was early shown (Kilbourne and Horsfall, 1951) to transform benign into fatal infections in adult mice. The effect of cortisone is largely directed to the heart and results in extensive myocardial lesions. The cortisone does not influence virus multiplication, which proceeds equally in its absence, but rather acts synergistically (Kilbourne et al., 1956)

The appearance of hepatitis has been unpredictable. Hepatitis leading to frank icterus and gastro-intestinal hemorrhage has been associated with some Group-B virus infections but inconstantly The lesions are usually less extensive and consist again of small areas of degeneration and even necrosis of parenchymal cells. It is not difficult to distinguish between these lesions and those due to mouse hepato-encephalitis virus, since the latter develops more slowly and is surrounded by a fairly characteristic inflammatory reaction. The occurrence in the liver sinusoids of large refractile cells, possibly derived from the Kupffer cells, noted by Pappenheimer et al. (1950), has not attracted the attention of other writers. A remarkable necrosis of the acinar epi-[illegible]

Pappenheimer et al. (1951). The process was remarkable in several respects. The destruction was limited to the acinar structures, the islands of Langerhans and ducts being spared; adult mice were susceptible as well as suckling animals. In the older mice, none of the other Group-B lesions occurred. The older mice characteristically survived and showed evidence of chronic pancreatic insufficiency, loss of weight, hypoproteinemia and at times anasarca.

The discrepancy between these observations and those of Gifford and Dalldorf (1951) were resolved when it was learned that the pancreatotropism of the viruses used was irrevocably lost following prolonged brain-to-brain passage. It was present in the same strain on reisolation from the human specimen and could be maintained by passage of visceral suspensions and intensified by pancreas transfers. Pancreatic lesions have been rather frequently associated with certain strains and less so with others. The method of maintaining the virus and strain differences apparently both play a part.

The remarkable events that take place in the pancreas have been studied by means of electronmicrographs (Robertson, 1954). Vacuoles were found in the cytoplasm within 18 hours following infection. They coalesced until the cytoplasm was filled with them. In addition laminated bodies appeared as well as inclusions, sometimes as large as 5 mμ.

Howes (1954) successfully titrated several Group-B strains in weaned mice, using pancreatic necrosis as the criterion of infection. His method consisted of injecting trypan blue intraperitoneally 4 hours before the mice were killed. The dye made the pancreatic lesions sufficiently conspicuous to read grossly.

Gravid mice become increasingly more susceptible to infection with a pancreatotropic strain of B-1 virus during the last week of pregnancy. A Group-A virus did not have such an effect (Dalldorf and Gifford, 1954).

The effect of whole body radiation on young adult mice infected with the Powers (B-4) Coxsackie virus was an increase in the titer and the persistence of the virus Mortality was little affected (Cheever, 1953).

Coxsackie-B viruses rapidly multiplied in HeLa tumor masses transplanted in the peritoneal cavity of rats and, on serial passage through rat-HeLa tumors, developed increased capacity for destroying solid carcinomata in vivo (Suskind et al., 1957)

INFECTIONS WITH BOTH POLIOMYELITIS AND COXSACKIE VIRUSES

The first attempts to determine whether Coxsackie and polioviruses interfere were made with Group-A viruses (Howitt and Nichols, 1952; Melnick, 1950) No effect was demonstrated. Later it was learned that Group-B viruses exert a sparing effect on experimental poliomyelitis in mice (Dalldorf, 1951, Sulkin et al, 1953, Stanley, 1952, Domok, 1957) The Group-A viruses do not have such an effect—further evidence of the considerable biologic differences between the groups. Group-B viruses have also been shown to interfere with the survival of cells subsequently inoculated with poliovirus in vitro This was first demonstrated by Le Bouvier (1954) and has been confirmed by De Lustig and Brieux (1957) As might be expected from the mouse experiments, a Group-A virus had no such effect (Ledinko and Melnick, 1954).

The possibility that interference occurs in nature has been discussed The evidence consists of the frequent observation that paralytic poliomyelitis has occurred infrequently during outbreaks of Bornholm disease and evidence of an inverse relationship between the isolation of Group-B viruses and the incidence of paralytic disease (Dalldorf, 1955; Dalldorf and Albrecht, 1955). It is noteworthy that the opposite has been noted regarding Group-A viruses and paralytic poliomyelitis This was true of the patients from whom the original Coxsackie virus was isolated, both of whom were paralyzed It was true the following year of 2 small outbreaks in New York (Dalldorf, 1952) and of an unusually severe epidemic in Easton, Pa (Melnick et al, 1951) Poliomyelitis virus was isolated from 27 of 36 patients, and Coxsackie virus from 27 of 42 that were tested. In 24 instances type 1 virus was isolated. The association of the two was so intimate that the suggestion was made that the Coxsackie infection might well have been a predisposing factor of the paralysis Similar, if less striking examples, are commonplace The experience in the South African Institute for Medical Research (1955, 1956) is representative of the results in many laboratories where extensive investigations have been undertaken

In 1955 and 1956 Group-A viruses alone were isolated from patients with paralytic poliomyelitis Of 27 paralyzed patients studied in 1955, 23 yielded poliovirus, and 5 Group-A viruses as well. In 1956 polioviruses and Group-A viruses were associated in 17 patients, none of whom yielded a Group-B virus The greater association of poliovirus with an A rather than a B virus was significant statistically.

Isolated	17	0

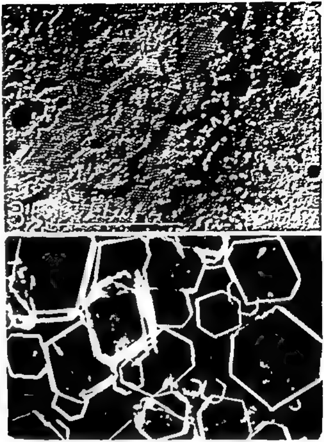
The probability of such a distribution occuring by chance = 0 0079

ETIOLOGY

Viruses of the Coxsackie group are relatively small and pass readily through bacteria-tight filters without significant loss in titer Results of filtration through gradocol membranes of known porosity indicate that the diameters of Group A, Types 1, 4 and 9, and Group B, Types 1 and 2, are about 20 to 29 mμ (Quigley, 1949, Himmelweit et al., 1950; Melnick et al, 1951, Melnick, 1955) This was true of virus contained in human feces, in the brain or the muscle of experimentally infected mice, and in infected tissue culture fluids The calculation of size is based on a factor of 0 64 multiplied by the size of the limiting pore diameter (i e, the A P D through which the virus just passes, or the average between the smallest A P D. fully passing the virus and the largest holding it back) (Black, 1958).

Ultracentrifugation in the partition cell of the analytical rotor, or through sucrose gradients in tubes in an angle rotor, yielded sedimentation constants of about 150 S and estimated diameters of about 25 to 30 mμ for the A-1, 2, 4 and 10 and B-1 and 2 strains studied (Melnick et al., 1951; Breese and Briefs, 1953) Direct examination of purified preparations of A-2, 4 and 10 in the analytical

FIG. 91. Coxsackie virus A-10 An electronmicrograph of a purified preparation (Breese, S S, Jr, and Briefs, A, 1953, Certain physical properties of a herpangina strain and a pleurodynia strain of Coxsackie virus, Proc. Soc. Exper. Biol. & Med 83, 119-122) The lower photograph is of the crystalline form of the same virus (Mattern, C. F. T., and DuBuy, H. G, 1956, Purification and crystallization of Coxsackie virus, Science 123, 1037-1038)



ultracentrifuge and in the electronmicroscope yielded values of 28mμ (see Fig 91) (Breese and Briefs, 1953; Mattern and DuBuy, 1956)

Coxsackie viruses are relatively stable Suspensions of virus may be preserved frozen at −70° or −20° C. for long periods without significant loss in titer Viral activity is also maintained when specimens of infected tissue are stored in 50 per cent glycerol or horse serum at room temperature for as long as 70 days, and in a refrigerator for over a year (Melnick and Ledinko, 1950) Like poliomyelitis viruses, these agents withstand exposure to a wide range of pH, i e, pH 2.3 to 9 4 for 1 day and 4 0 to 8 0 for 7 days (Robinson, 1950) Aqueous suspensions of certain strains *were not inactivated at 55° C. for 30 minutes* but were at 60° C. for the same period, temperatures 10° to 20° C. higher were required for inactivation when the virus was suspended in milk, cream, or ice cream (Kaplan and Melnick, 1952) Coxsackie viruses were not inactivated or not inhibited in vitro or in vivo by a variety of chemotherapeutic agents, including penicillin, streptomycin, chloramphenicol, oxytetracycline and viscosin Certain commonly used antiseptics, including ethanol (70%), Lysol (5%), Roccal (1%) and ether, also failed to inactivate the agents However, treatment with 0 1 N HCl or 0 3 formaldehyde, effected rapid inactivation (Melnick, 1951).

Group A, type 10 has been purified from suckling mice carcasses by a combination of salting out and ultracentrifugation procedures Upon storage at 4° C., the virus particles *form dodecahedral crystals about 100 mμ in* size (see Fig 91) The crystals have a titer of 10^{13} LD_{50} per cm^3. As this volume con-

tains about 4.6×10^{16} particles of 28 mμ diameter, the ratio of number of particles to number of infective units was about 4,600 to 1. A similarly large ratio of noninfectious to infectious particles could be calculated in the crude infected tissue suspensions (Mattern and DuBuy, 1956). About 4 per cent of the virus particle is made up of nucleic acid; the preliminary evidence suggests that it is of the ribose type

DIAGNOSIS

Diagnosis of infection by a Coxsackie virus may be suggested by clinical and epidemiologic manifestations, particularly of aseptic meningitis, pleurodynia, herpangina, or myocarditis occurring in the newborn However, confirmation must be obtained in the laboratory by the recovery of the virus from specimens of blood, cerebrospinal fluid, feces or oropharyngeal swabbings collected during the acute phase of illness and demonstration of a related increase in neutralizing antibodies against the virus in serum collected from patients during the acute and the convalescent stages of illness. Tissue culture technics have to a considerable extent supplemented but not supplanted the use of suckling mice for these purposes Rises in titer of complement-fixing antibodies against heterologous as well as homologous Coxsackie viruses occur in human serum following infection by these agents Hence, determinations by this technic are of limited diagnostic value It should be emphasized that demonstration of *infection* by a Coxsackie virus can be achieved by laboratory methods, but diagnosis of *disease* caused by one of these agents requires careful correlation of supporting clinical, epidemiologic and laboratory evidence

Differentiation of aseptic meningitis caused by a Coxsackie virus from mumps meningo-encephalitis, lymphocytic choriomeningitis, infection by ECHO viruses and other viral agents or by leptospira may be indicated by clinical and epidemiologic findings. Diagnosis of infection with these agents can usually be established by appropriate serologic tests and also in some instances by recovery and identification of the responsible agent, especially when obtained from the cerebrospinal fluid In view of the acute self-limited course of infection with Coxsackie virus in most instances and the paucity of associated neurologic signs, differentiation from bacterial meningitis, multiple sclerosis, or space-occupying intracranial lesions such as tumor, abscess, or hemorrhage, usually should not be difficult. Differentiation of Coxsackie virus infection from nonparalytic poliomyelitis in individual patients with aseptic meningitis does not appear to be possible on the basis of clinical findings alone, although persistence of spasm in isolated muscle groups is more suggestive of poliomyelitis. Although Coxsackie viruses have been recovered frequently from patients with a clinical picture of paralytic poliomyelitis, a causal relation of Coxsackie virus to paralytic disease is relatively uncommon and probably limited to only a few types, In most instances the association is probably coincidental Coxsackie and poliomyelitis viruses have been found together in the feces of individual patients with or without paralysis. On the basis of present knowledge, it appears reasonable for the clinician or the epidemiologist to consider and treat any acute febrile illness with associated paralysis as poliomyelitis until convincing evidence in support of an alternative diagnosis is demonstrated.

Epidemiologic evidence of seasonal and of local or regional prevalence is of value in the

be differentiated in individual patients from other causes of thoracic pain, particularly pneumonia, pleurisy and coronary thrombosis and from other causes of abdominal pain including acute appendicitis, peptic ulcer, disease of the gallbladder and acute pancreatitis. The superficial distribution of pain, the absence of deep abdominal or rectal tenderness, a relatively normal blood leukocyte count, and the absence of abnormal roentgenologic findings should aid in the diagnosis of infection by Coxsackie virus which can usually be verified by recovery of the virus and demonstration of an associated specific antibody response in the patient's serum The complication of orchitis in patients with pleurodynia or aseptic meningitis must be differentiated from mumps, a virus infection in which meningo-encephalitis often without parotitis may also be a manifestation

Diagnosis of herpangina is suggested by the acute self-limited course of the disease and the presence of typical faucial lesions The condition most likely to be confused with herpangina is infectious gingivostomatitis due to herpes simplex virus which may be associated with vesicular or ulcerative lesions in any part of the oral cavity, at mucocutaneous junctions, and in the skin Coxsackie virus infections are seasonal and may be epidemic, whereas herpes simplex infections are sporadic and without particular season distribution Coxsackie and herpes simplex viruses are both readily isolated in suckling mice and in tissue cultures. They can be identified and differentiated by various technics in the laboratory The oral manifestations of other conditions which may occasionally require differentiation from herpangina include the exanthems of acute exanthematous diseases and lesions associated with moniliasis, infectious mononucleosis, heavy metal poisoning, deficiency diseases and certain blood dyscrasias

Myocarditis in newborn infants must be differentiated from other forms of neonatal infection A diagnosis may be suggested by concurrent Coxsackie virus infection in the community and particularly in the mother at about the time of delivery The possibility of infection by a Coxsackie virus should be considered in any epidemic occurrence of severe disease in newborn infants and in newborn infants with signs of cardiorespiratory embarrassment

Because the clinical picture of infection by Coxsackie viruses is probably still incomplete, the possibility of infection by one of these agents should also be considered in cases of acute unexplained infections, particularly those affecting the neromuscular or cardiovascular systems and the pancreas, and especially when they occur in characteristic seasonal and epidemic distribution

It should be remembered that in a strict sense etiologic diagnosis may be difficult or complicated, since a feature of enteric virus infections is the tendency toward multiple infection Since it is probable that a number of enteric viruses have not yet been identified and may not be recognized by current technics, the possibility remains of the presence of undetected agents Moreover, a thorough search for the known viruses is laborious and hardly suitable for routine use A first principle should be that, once an agent has been isolated and identified, the original specimen be retested in the presence of specific antiserum for the agent recovered In this way additional viruses may not infrequently be found

The relative efficiency of isolations of Group-A viruses in suckling mice and monkey kidney cell cultures may be in the nature of 19 to 1 as judged by the prevalence of types in the past (Dalldorf, 1957) This obviously will vary from time to time with the proportion of cytopathogenic strains As a rule, a search for Coxsackie viruses cannot be considered to be satisfactory if mice are not inoculated, and it is well to inoculate 3 litters (randomized) by the subcutaneous, the intraperitoneal and the intracerebral routes The relative advantage of 2 routes of inoculation was determined by Johnsson (1955e) (cf Table 16). In the author's experience 3 routes afford further advantage

The Group-B viruses are much more suitable for isolation in tissue culture Monkey kidney and human amnion cells are superior in degree to HeLa cells (Table 18). At times Group-B viruses have been isolated more readily in tissue culture than in mice The reverse occurs less frequently. In the case of A-9, isolation in tissue culture is more efficient than in suckling mice. This was conspicuously true of the epidemic strains serologically related to ECHO 9 that occurred in Europe during 1955 and 1956 Many of these strains could not be directly isolated in mice, although they were, as a rule, pathogenic for mice after growth on monkey kidney cells

Methods that have been used successfully in the isolation, the grouping and the typing of Coxsackie viruses have been published (Dalldorf and Sickles, 1956) Grouping is possible from observation of the mice and histologic examination Typing of Group-B strains requires the use of the individual antisera The Group-A typing sera may be combined into two pools if their titers are satisfactory. The first represents Types 1, 4, 6, 7 and 9, and the second, Types 2, 3, 5, 8

(See facing page for notes)

sackie viruses have been of minor degree and are taken into account in the assembling of the Group-A pools Typing sera have been prepared under the auspices of the Committee on Enteroviruses of the National Foundation for Infantile Paralysis

Etiologic diagnosis depends on isolation of the virus, since the number of types is too large to justify serologic tests unguided by knowledge of the type of virus that may be responsible In the presence of an epidemic, of course, this rule may be broken Infection should be confirmed by serologic tests, preferably neutralization tests in tissue culture or mice The complement-fixation reaction is of limited diagnostic value but may be used to advantage in typing This is especially true of Group-A viruses (Beeman et al, 1952, Contreras et al, 1952)

TREATMENT

No form of therapy is known which specifically affects infection induced by viruses of the Coxsackie group Various supportive and symptomatic measures may ameliorate certain features of the illnesses

EPIDEMIOLOGY

Viruses of the Coxsackie group have been encountered in all parts of the globe Isolations have been made mainly from human feces, pharyngeal swabbings, sewage and flies Widespread distribution is also indicated by the detection of antibodies in serum from individuals collected in different parts of the world and by the capacity of gamma globulin prepared from pooled human serum to neutralize all of the Coxsackie viruses thus far tested Evidence that the capacity of gamma globulin to neutralize Coxsackie viruses is an indication of previous specific antigenic experience is supported by the results of neutralization tests with serum collected from Eskimos in northern Alaska (Banker and Melnick, 1951), which revealed a population heavily exposed to A-4 and A-10, less so to A-1, and not at all to B-1 and B-2 In tests with specimens of feces which were collected in the same area, strains of Type 10 were isolated from each of 2 Eskimo children.

Information concerning the geographic and temporal distribution of individual types has become extensive. The earliest studies were suggestive Thus, in 1948, B-1 viruses were prevalent in Connecticut and Rhode Island (Curnen et al., 1949) as well as in New York (Dalldorf and Gifford, 1951) The same type was retrospectively proved to have been present in Massachusetts in 1947 (Weller et al., 1950) but thereafter was found infrequently for a number of years The striking prevalence of B-3 during 1951 in many parts of the world has been noted (Dalldorf, 1955) and has now been matched by the wave of infections due to the virus designated, at present, as ECHO, Type 9. These are examples of the pattern that has characterized many epidemics.

Most Coxsackie viruses have been recovered from specimens collected during the summer and the early fall Although this reflects to some extent the fact that these agents were first detected and later sought in the course of investigations on poliomyelitis, additional evidence has been obtained to indicate that Coxsackie viruses actually are encountered more frequently during the summer months. In epidemiologic surveys during 1949 and 1950, investigators (Huebner et al, 1950a, 1951, Cole et al., 1951) tested samples of feces collected at different times from individual inhabitants of a residential community near Washington, D C Isolations of virus were made almost exclusively in July, August and September.

Notes for Table 18

(Coxsackie viruses of Group B and A-9 produce round plaques on monkey kidney cells under agar, resembling those of the poliovirus [illegible]

† B-2 and B-4 strains more erratic on HeLa cells than B-1, 3, 5

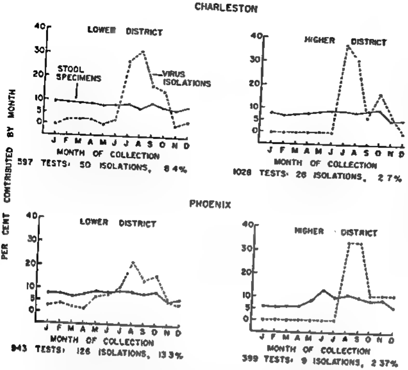

FIG. 92. Stool collections and enteric virus isolations. The cumulative score for each month during a 3-year period The specimens were collected from healthy children in Charleston, W. Va, and Phoenix, Ariz, during a nonepidemic period (Melnick, J. L, 1957, Special publication of the New York Acad. of Sc. *5*, 365-381)

In one study (Melnick and Ledinko, 1951) neutralizing antibodies to the local Coxsackie virus, A-4, were present in the spring in 90 per cent of the newborns but in only 15 per cent in the 6- to 12-month-old group The incidence was higher with increasing age reaching the adult level of 85 per cent in the 7- to 9- and 10- to 14-year-old age groups During the summer there was an increase in antibodies in all age groups except that of 7 years and over in which the adult level had already been reached Thus, in all children 6 years of age and under, 42 per cent were positive in May

economic group and 33 per cent for those in the lower group As in the case of

of 50 per cent dropped to 10 per cent in the 6- to 12-month age group, following which it progressively rose to reach 65 per cent in the 7- to 9-year age group This was of the same order as the adult level, and it was at this period that the neutralizing antibodies also reached the adult level. However, for the complement-fixing antibody there was a marked fall to 25 per cent positive in the 10- to 14-year age group, in contrast with the maintenance of the neutralizing antibody level. As with the neutralizing antibodies, an increase in complement-fixing antibodies took place during the summer in all age groups except in those 7 years and over In view of the fact that over 80 per cent of the children 7 years of age and

years and under, showed a 4-fold or greater drop in antibody titer during the summer In keeping with the maintenance of neutralizing antibody levels and decrease in complement-fixation antibody levels, it is worth noting that practically all children with complement-fixing antibodies had neutralizing antibodies as well.

An attempt was made to recover Coxsackie viruses from 860 patients in New Haven, Conn, who had acute febrile illnesses between March, 1950, and April, 1951. Forty-four strains were isolated, 36 of which were encountered in the period from July to October (Curnen and Godenne, 1952).

Coxsackie viruses have been recovered from

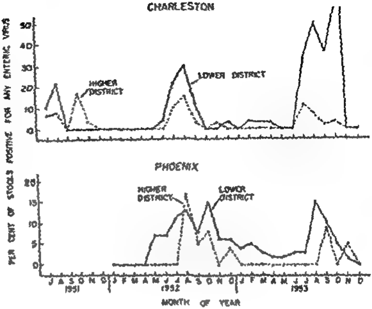

FIG. 93 The results of the Charleston-Phoenix study arranged to show the recurrent seasonal incidence of enteric virus excretion among normal children (Melnick, J L, 1957, Special publication of the New York Acad of Sc *5*, 365-381)

persons of both sexes and more frequently from children than from adults However, sufficient data are not yet available to determine accurately the incidence according to sex, race, or age-specific attack rates, this is particularly true of infections caused by different types.

Consecutive tests for several years for Coxsackie viruses in urban sewage and flies have been carried out in 6 states (Melnick et al, 1954a, b, Kelly et al, 1955, Kelly, 1957) In almost every urban area studied, virus appeared in some of the specimens collected in the summer and the fall Virus was detected in the community during the cold months but was not widely disseminated, for it was *only* a rare winter specimen that yielded virus. Even though present each summer, the frequency of virus recovery during the months of peak occurrence varied in the same community from year to year, ranging from 10 to 100 per cent The recovery of Coxsackie viruses was more regular from sewage than from flies in the same area In Muskegon, Mich, where in 1 year Melnick et al (1954) isolated 34 Coxsackie strains from sewage, 26 belonged to a single antigenic type, A-1. In Topeka, Kans, Coxsackie viruses were recovered through the summer and the fall of 1 year, but A-5 was present in the summer, and it was replaced by A-6 in the fall Thus the long persistence of virus for several months in a residential area, or its reappearance after a short period, may be due to the serial dissemination of new types of virus rather than to recurring waves of infection by the original virus In Albany, N Y, Kelly (1957) observed similar changing annual patterns In 1953, A-5 and A-6 were frequently isolated, but 1 year later the predominant types were A-4, A-8 and B-2 In these respects all of the recognized enteric viruses behave similarly

In a longitudinal study recently reported (Melnick, 1957b, Honig et al, 1956) approximately equal numbers of stools were collected each month from normal children living under contrasting environments in Charleston, W Va, and Phoenix, Ariz As shown in Figures 92 and 93, almost all of the virus isolations were made in the summer and the fall, except from the lower socio-economic district of Phoenix where viruses were recovered throughout a larger part of the year Figure 93 illustrates the recurrent seasonal incidence of enteric virus excretion among normal children

The frequency of virus excretion in the lower socio-economic district of each city was 3 to 6 times as great as in the middle to upper middle-class districts with good environmental sanitation If the combined figures are examined (Table 19) of 1,540 specimens tested in the lower districts, 176 (11 4%) were posi-

TABLE 19. PER CENT DISTRIBUTION OF ENTERIC VIRUSES ISOLATED FROM HEALTHY CHILDREN IN POPULATIONS OF CONTRASTING SOCIO-ECONOMIC LEVEL DURING A NONEPIDEMIC PERIOD (1951–53) *

Population Group	Number of Specimens Tested	Per Cent Yielding Viruses

Lower	1540	2.8	2.1	6.6	11.4
Upper	1427	0.6	1.3	0.6	2.6

* From Melnick (1957b)

tive, whereas in the upper districts only 2.6 per cent (37 of 1,427 specimens tested) yielded virus Among the 213 viruses isolated in monkey kidney cultures, 52 per cent were ECHO viruses, 24 per cent were polioviruses, and 24 per cent were Coxsackie viruses

Similarities in the epidemiology of poliomyelitis and infection by Coxsackie viruses may be briefly summarized Both poliomyelitis and Coxsackie viruses induce in man infections associated with specific antibody responses In the human host both agents may be carried for some time and may cause either recognizable disease or inapparent infection. They are encountered most frequently at the same time of year Both agents may be recovered not only from man but also from flies and sewage and at times may be found together in the same specimen When both kinds of virus are found together in a patient with or without paralysis, it is not possible to determine precisely the extent to which each agent contributes to the observed [illegible]

may [illegible] above).

CONTROL MEASURES

Specific measures to control infection by Coxsackie viruses have not been devised These agents may be distributed by means of the oropharyngeal secretions and the feces of infected persons, many of whom remain undetected Flies and cockroaches may harbor and transport Coxsackie viruses, but whether they are of importance in the transmission of Coxsackie-virus diseases from person to person has not yet been determined Because of the unusual stability of Coxsackie viruses at ordinary temperatures and their resistance to alcohol and other substances commonly used as antiseptic solutions, decontamination of objects which cannot be boiled or autoclaved may not be achieved by conventional methods However, Coxsackie viruses can be inactivated rapidly by 0.1 N hydrochloric acid or 0.3 per cent formaldehyde No reports have appeared on the efficacy of vaccines in prophylaxis

The ECHO Virus Group

INTRODUCTION

The ECHO (enteric cytopathogenic human orphan) viruses comprise a group of agents brought together chiefly because they infect the human intestinal tract and because they can be isolated only in certain tissue cultures Although only recently recognized, certain types are already known to cause aseptic meningitis with or without rash, febrile illnesses with or without rash, and diarrheal diseases in infants and children during the summer months. Twenty-four antigenic types have been identified thus far, and additional types are in the process of classification

HISTORY AND STATUS OF ECHO GROUP

The refinement of tissue culture methods and the expansion of their use into the field of virology led to the isolation of large numbers of hitherto unknown viruses that ordinarily fail to produce disease in laboratory animals It early became apparent that these

with the aseptic meningitis syndrome (Robbins et al, *1951*; *Steigmann* et al, *1953*; Melnick, 1954) and that multiple types exist (Melnick, 1954, Ramos-Alvarez and Sabin, 1954) As more investigators entered the field, more and more of these untypable agents were recognized. Because their relationship to human disease was unknown, and because they failed to produce illness in laboratory animals, including infant mice, they were called "orphan" viruses or human enteric viruses, a name later changed to *Enteric Cytopathogenic Human Orphan* viruses or ECHO viruses (Committee on the ECHO Viruses, 1955) A co-operative study by Melnick,

duce disease in laboratory animals, including newborn mice

During the past decade, a large number of hitherto unknown viruses have been found in the intestinal tract of man by use of newborn mice and tissue cultures for their isolation These viruses include the 19 group A and 5

many investigators (Johnsson, 1957; McLean and Melnick, 1957, Quersin-Thiry et al, 1957, Boissard et al, 1957; and others) that

a large proportion of epidemic strains recovered in Europe in 1956 produced paralysis in newborn mice after inoculation of the large amounts of virus contained in undiluted tissue culture fluid. *The paralysis was found to be* the result of muscle lesions indistinguishable from those produced by the Coxsackie A viruses However, unlike the classic Coxsackie A viruses, the original human specimens *containing the ECHO 9 viruses quite regularly* failed to produce paralysis, and even after passage in tissue culture there was great variation in the number of strains that acquired the capacity to produce paralysis with large

property of ECHO [illegible] viruses (Eggers and Sabin, *1958) indicated* great variation among different strains, with some strains (like the original prototype) the virus does not even multiply in newborn mice, while with others even 3 TCD_{50} may result in inapparent multiplication, and very large doses are required to produce paralysis. Serial passages in mice can select more paralytogenic virus particles; therefore, occasionally it might be possible to isolate certain strains by passage in mice as was accomplished by Gear and Dalldorf (personal communication). Since most other ECHO viruses have not been studied in a similar manner, it is not known how many others may possess variants similar to those of ECHO 9.

Among the 19 established Coxsackie A viruses there is only one type (A 9) that in its naturally occurring state is cytopathogenic for monkey kidney tissue cultures—the *optimum medium for the ECHO viruses—and* newborn mice are in most instances not sufficiently susceptible to permit its isolation directly from human material (Melnick, 1955, Honig et al, 1956, Habel et al, 1957). Thus, the question has arisen whether ECHO 9 virus should be transferred to the Coxsackie A group because some of its variants produce paralysis in newborn mice or Coxsackie A 9 virus should be transferred to the ECHO group because most of the naturally occurring strains possess the predominant characteristics of the ECHO viruses

It is obvious that no single property can be used to classify viruses, and especially when that property is absent in the majority of naturally occurring virus particles Not all naturally occurring viruses that are pathogenic only for newborn mice (e g., the dengue, the sandfly fever or the Sindbis viruses) or that produce paralysis with muscle lesions (e g., some of the encephalitis viruses) can be grouped with the Coxsackie viruses, nor can *all variants of viruses (e g, dengue) capable* of producing paralysis with lesions in the anterior horn cells of the spinal cord of monkeys be grouped with the poliomyelitis viruses Yet it is becoming increasingly apparent that *some variants of the Coxsackie viruses,* notably A 7 and A 14, as well as some of the ECHO viruses, can produce neuronal lesions in monkeys and that some variants of the polioviruses may lack the capacity of producing *either paralysis or neuronal lesions in* monkeys and chimpanzees In the Coxsackie B group there is also a certain proportion of naturally occurring strains that lack the

apparent that many properties, such as approximately similar size, certain cellular af-

myelitis viruses to warrant their inclusion in a single family of human *enteroviruses* (*Committee on the Enteroviruses, 1957*). The adenoviruses, herpes simplex and perhaps also the mumps and the influenza viruses, although affecting predominantly the respiratory and the upper alimentary tracts, may occasionally *be found or even multiply in the* intestinal tract. However, their size and other properties serve to distinguish them from the true enteroviruses The size of many of the viruses now in the Coxsackie and the ECHO *groups still remains to be determined.* On this basis at least one of the viruses now in the ECHO group, i e, ECHO 10, probably will form a distinct group, for different antigenic variants of this virus have been found by *gradocol membrane* filtration to have a size of 60 to 90 mμ (compared with 12 to 20 mμ by similar methods of measurement and calculation for the polioviruses and many of the ECHO and the Coxsackie viruses) and to be implicated in respiratory as well as enteric infections (Sabin, 1957a) Furthermore, mouse pathogenic variants producing lesions comparable with those of Coxsackie [illegible] viruses have been segregated from some of the strains (Dalldorf, 1957a; Sabin, 1957a), and at least one of these variants has been *found to multiply* in chick embryos (Dalldorf, 1957a). Furth

in the Coxsackie and the ECHO groups will ultimately provide the basis of a more definitive classification

It was first postulated (Committee on the ECHO Viruses, 1955) that whenever an ECHO virus was established as the etiologic agent of a clinically distinct disease, it would be removed from the ECHO group However, subsequent experiences have demonstrated that thus far the ECHO viruses have been established as etiologic agents only of clinical syndromes which may be caused by a variety of bacteria or viruses For example, ever since their first isolation and recognition, a number of different enterovirus types have been shown to be associated with, and responsible for, aseptic meningitis. However, because this is a syndrome rather than a clinically distinct disease, it will have to be designated in a particular patient as *aseptic meningitis due to ECHO type 6*, or whatever other virus type happens to be involved The same is true of the febrile illnesses with exanthem, or of the diarrheal infections in which ECHO viruses have been incriminated.

CLINICAL PICTURE

The incidence of clinically recognized disease produced by ECHO viruses varies with the type and the strain of virus in a manner comparable with various types and strains of poliovirus The clinical manifestations resulting from infection with certain types of ECHO virus are now based partly on observations during epidemics in which one type of ECHO virus predominated, as in certain outbreaks of the aseptic meningitis syndrome, febrile illnesses with exanthem, and infantile diarrhea, or on controlled studies of summer diarrheal diseases in early childhood The clinical manifestations associated with infection by different members of the enterovirus family are listed in Table 20 For establishment of etiologic association it was necessary to show a much higher prevalence of these viruses among patients with the disease than among noncontact healthy individuals of the same age and socio-economic status living in the same area at the same time as the patients It was also necessary to establish in individual patients the absence of concurrent infection with other agents already known to cause the same clinical syndrome Additional evidence of the role of ECHO viruses in the clinical

TABLE 20 CLINICAL MANIFESTATIONS ASSOCIATED WITH INFECTION BY ENTEROVIRUSES

Polioviruses

1 Paralysis (complete to slight muscle weakness)
2 Aseptic meningitis
3 Undifferentiated febrile illness, particularly during the summer

Coxsackie Viruses, Group A

1 Herpangina (Types 2, 4, 5, 6, 8, 10)
2 Undifferentiated febrile illness, particularly during the summer
3 Aseptic meningitis (Types A 7, A 9)
4 Febrile illness with rash (Type A 9)

Coxsackie Viruses, Group B

1 Aseptic meningitis
2 Pleurodynia
3 Undifferentiated febrile illness with pharyngitis
4 Myocarditis or encephalomyocarditis during neonatal period and early childhood
5 Mild paralysis (?) or encephalitis

ECHO Viruses

1 Aseptic meningitis (Types 2, 3, 4, 5, 6, 9, 14, 16, 21)
2 Febrile illness with rash (Types 4, 9, 16 and probably others)
3 Undifferentiated febrile illness
4 Mild paralysis (?) (Types 6, 9) or encephalitis (Type 9)
5 Summer diarrhea of infants and children (Type 18 and others)

manifestations to be described here was obtained by demonstrating antibody development during the course of the illness The frequent presence of the virus in the cerebrospinal fluid, particularly in ECHO 9 infections, provided further evidence for an etiologic association with the aseptic meningitis syndrome For the present it seems best not to generalize but to describe separately the clinical picture observed in association with infection by individual ECHO viruses

ECHO 4 Two outbreaks are on record. (1) In Marshalltown, Iowa, and vicinity in 1955 (Lehan et al, 1957, Chin et al, 1957) the clinical manifestations consisted predominantly of the aseptic meningitis syndrome and some associated minor illnesses but without exanthem, and (2) in Sweden in 1956 (Johnsson, 1957) in which an exanthem was

observed in some of the patients. In the Marshalltown outbreak, the onset was characteristically abrupt with fever and severe headache, frequently localized in the retrobulbar area. Disturbances of the alimentary tract in the form of nausea, vomiting or diarrhea were recorded in about 70 per cent of the patients and sore throat in about 40 per cent. Irritability was common, and pain in the muscles of the lower extremities was a symptom in about 40 per cent. All patients in the aseptic meningitis group complained of stiffness of the neck or the back or both, and this could be confirmed by physical examination; however, none exhibited either the Kernig or the Brudzinski signs. There were no abnormal reflexes. Minor transient weakness of one leg was noted in 2 of the 53 patients with the aseptic meningitis syndrome, but it was not indicated whether these might have been the patients from whom both ECHO 4 and polioviruses were recovered (4 of 21—Chin et al., 1957).

The fever was low grade (99° to 102° F.) and lasted 3 to 5 days in the patients with aseptic meningitis and only 2 to 3 days in those without "meningeal signs." Except for the shorter duration and the absence of neck or back stiffness, the patients in the minor illness group (45% of the illnesses in a surveyed population during this epidemic) presented essentially the same clinical manifestations as the aseptic meningitis group. Except for "mild to moderate lymphoid hyperplasia of the posterior pharynx" there were no positive findings on physical examination. The peripheral white blood counts were within normal limits. The number of cells in the cerebrospinal fluid of the patients with aseptic meningitis varied from 16 to 900 (average 200), of which approximately 80 to 97 per cent were lymphocytes, the sugar was normal, and the protein was only occasionally slightly elevated, the highest being 67 mg. per 100 ml.

Only about 50 per cent of the cases occurred in children under 14 years of age, and multiple familial cases were not uncommon. The incubation period could not be determined. While more than 50 per cent of the secondary cases in families occurred within 5 days, the longest interval was 21 days. No clinical data are available on the Swedish outbreak, except for the occurrence of an exanthem.

ECHO 6. This type of ECHO virus has been rarely encountered except in association with clinically recognized disease. At the Yale laboratory it was found only once among 212 enteric viruses recovered from healthy children (Melnick, 1955) and in the Cincinnati laboratory only once among more than 380 enteric cytopathogenic viruses recovered from healthy children in Cincinnati and Mexico.

The role of ECHO 6 virus in the aseptic meningitis syndrome is based on reports of its occurrence in 5 outbreaks between 1952 and 1955 in the U. S. and Sweden. In 1952 in Washington, D. C. (Habel et al., 1957)

ular study no ECHO 6 viruses were recovered from a control group of 296 ward and dispensary patients and 2 strains were recovered from 127 healthy children in the community. In 1954 in Sweden (von Zeipel and Svedmyr, 1957) 34 strains of ECHO 6 were found among 51 enteroviruses (4 polioviruses, 2 Coxsackie B 4, 2 Coxsackie A 7, 37 ECHO, 6 unidentified) recovered from 130 patients with a diagnosis of nonparalytic poliomyelitis or aseptic meningitis. During the same period no ECHO or Coxsackie viruses were found among 15 enteroviruses (all poliovirus) recovered from 33 patients with a diagnosis of paralytic poliomyelitis, and only 4 ECHO 6 viruses were found among 5 enteroviruses (1 Coxsackie B 4, 4 ECHO 6) and 1 adenovirus recovered from 128 individuals in a control group of healthy children or patients with other diagnoses. In 1954 in Boston (Kibrick et al., 1957) 40 strains of ECHO 6 were found among 65 enteroviruses (16 polioviruses, 5 Coxsackie, 43 ECHO, 1 unidentified) and 4 adenoviruses recovered from patients with a clinical diagnosis of poliomyelitis. In 1955, during the severe and extensive type 1 poliovirus epidemic in Boston ECHO 6 was again recovered from 10 patients with a diagnosis of nonparalytic poliomyelitis (Kibrick et al., 1957). In 1955 ECHO 6 was also prevalent in Connecticut (Davis and Melnick, 1956) where 21 strains were found among 69 enteroviruses (28 polioviruses, 16 Coxsackie, 25 ECHO) recovered from 137 patients with a

diagnosis of nonparalytic poliomyelitis, and only one strain among 45 enteroviruses (42 polioviruses, 1 ECHO 6, 1 Coxsackie A 9 and 1 Coxsackie B 4) recovered from 58 patients with a diagnosis of paralytic poliomyelitis. In western New York State in 1955, ECHO 6 was the predominating virus in an epidemic of "nonparalytic poliomyelitis," constituting more than 90 per cent of 172 cytopathogenic agents recovered in monkey kidney tissue cultures from patients and healthy household contacts (Karzon et al, 1956; Karzon, 1957). Ten strains of ECHO 6 virus were also isolated in 1955 from sporadic cases of aseptic meningitis in Washington, D C, California, Florida and Massachusetts (*Meyer et al., 1957*).

The clinical picture to be described here is based only on the manifestations observed in virologically proved cases (Davis and Melnick, 1956, Karzon et al, 1956; Kibrick et al, 1957, Meyer et al, 1957) The incubation period has been estimated at 3 to 5 days, based on the temporal sequence of cases within households (Kibrick et al, 1957). The disease affects children and adults The onset is characteristically abrupt with fever, severe headache and vomiting Sore throat was encountered in only 25 to 40 per cent of the patients Poorly defined abdominal pain was an occasional complaint, and diarrhea or constipation were absent or uncommon Stiffness of the neck and less often of the back appeared early in the majority of the patients and after an interval of several days of apparent well being in about 25 per cent of the patients, who exhibited a biphasic febrile and clinical course A convulsive onset was observed in a few patients, and generalized muscle pains were encountered with varying frequency in different outbreaks Fever was low-grade (100° to 102 6° F) and lasted 3 to 6 days Physical examination revealed mild or moderate stiffness of the neck or the back, or both, and occasional hamstring spasm Some depression of the superficial or deep tendon reflexes was occasionally found during the acute phase In the Holland, New York, outbreak where only ECHO 6 virus was recovered, some of the patients exhibited muscle weakness rated fair to poor by physiotherapists, at the time of discharge after several days of normal temperature, but no weakness, atrophy or spasm were found upon re-examination several months later (Karzon et al, 1956). In the 1954 Boston outbreak an orthopedic evaluation of 37 patients from whom only ECHO 6 virus was recovered designated the disease as paralytic in 22. Of the 22 cases classified as paralytic, 10 were placed in Grade I (score 0), i e., minimal weakness, 11 in Grade II (score 1 to 19) and 1 in Grade III (score 20 to 89) In most instances the mild to moderate degree of dysfunction disappeared with the passage of time. The muscles most frequently involved were the gluteus medius, the hip adductors and occasionally the gastrocnemius. Although it is possible that in a few instances there may have been concomitant infection with poliovirus, as was reported by others in isolated cases (Davis and Melnick, 1956; von Zeipel and Svedmyr, 1957), there were at least 3 patients with moderate muscle involvement in the Boston group, in whom this could be excluded because no neutralizing antibodies for any of the 3 types of poliomyelitis could be demonstrated (Kibrick et al, 1957).

There were no other significant clinical manifestations, adenopathy and splenomegaly were found in only 3 and 2 patients, respectively, in the Boston group None of the investigators noted the presence of rash, but during the summer of 1957 in Cincinnati a maculopapular eruption affecting the whole body, including the palms and the soles, was observed in one child, and a red, raised 2 to 3 mm. buccal lesion without exanthem, in its sibling during the course of a febrile illness associated with infection by ECHO 6 virus (Sabin et al, 1958b) In Sweden in 1954 serologic evidence of infection with ECHO 6 was observed in a patient with a diagnosis of erythema exudativum multiforme (von Zeipel and Svedmyr, 1957) *Febrile illnesses*, exhibiting all manifestations except those of meningeal irritation, as well as a few clinically inapparent infections, have been observed in household contacts of patients (Karzon et al, 1956; Kibrick et al, 1957)

The peripheral leukocyte counts were within normal limits or slightly elevated with neutrophils usually predominating. The leukocyte counts in the cerebrospinal fluid varied from 14 to 855 (the majority under 500) with polymorphonuclear cells predominating during the first few days after onset

and lymphocytes later on The concentrations of sugar and protein in the cerebrospinal fluid were either within normal limits or slightly elevated.

ECHO 9. The first strains of this type, originally designated as HE (human enteric) type 3, were recovered from healthy children during epidemiologically quiescent periods in Cincinnati and Mexico and represented only a small proportion of the large number of enteroviruses that were isolated (Ramos-Alvarez and Sabin, 1954, Ramos-Alvarez and Sabin, 1956) At the end of 1955 when this type of virus was renamed ECHO 9 there was only a single strain from a case of aseptic meningitis in West Virginia, and the importance of this virus as a cause of large epidemics of aseptic meningitis and febrile illnesses with rash did not become apparent until hundreds of strains recovered from patients in Belgium, Holland, Britain, Germany and Sweden in 1956 were almost simultaneously reported as being serologically similar to ECHO 9 (Nihoul and Quersin-Thiry, 1957, Johnsson, 1957, Sauthoff and Mittelstrass, 1957, McLean and Melnick, 1957; Boissard et al, 1957) ECHO 9 was subsequently also identified as the predominant virus in 1956 in epidemics in Switzerland (Baumann et al, 1957), Denmark (Godtfredsen and von Magnus, 1957) and Canada (Laforest et al., 1957) Viruses recovered from small outbreaks in Britain in 1954 and 1955 (Boissard et al, 1957) as well as those recovered only by tissue culture methods (Archetti et al, 1956) from the extensive outbreak in Italy in 1955 that was reported under the name of "Meningonevrassite Coxsackiosica Marchigiana" (Russi and Fua, 1956) have also been identified as related to ECHO 9 (Dalldorf, 1957b) In Germany other investigators reported the same disease either as being due to a new type of virus that was not pathogenic for mice (Hennessen, 1956) or as "Coxsackie Meningitis" (Brohl et al., 1957) because after several passages in tissue culture the viruses were pathogenic for mice as previously described. In 1957 extensive epidemics of ECHO 9 disease affecting tens of thousands of people were studied in the U.S.A (Sabin et al, 1958a).

The spectrum of the clinical manifestations of ECHO 9 disease, based only on virologically proved cases, definitely includes the aseptic meningitis syndrome and an undifferentiated febrile illness with or without exanthem and enanthem, and occasionally more extensive involvement of the central nervous system. The occurrence of exanthem which was a frequent finding in most of the European and American epidemics was not observed in the extensive Italian outbreak of 1955 (Archetti et al, 1956) or in the epidemic in a Swiss village in 1956 (Baumann et al, 1957), and it is possible that the incidence and the kind of clinical manifestations may vary with different strains of the virus.

The usual incubation period has been estimated at 5 to 8 days, but there is suggestive evidence that occasionally it may be as long as 15 to 20 days. The onset was invariably with headache, usually severe and frontal, generalized malaise, irritability and weakness. Fever (101° to 103° F.) appeared usually simultaneously with these symptoms or was delayed for 1 or 2 days, although patients who are not conscious of having fever may exhibit elevated temperatures Moderate chills were observed in 15 per cent of patients. Other symptoms include sore throat (about 50%), nausea and vomiting and occasionally generalized abdominal pain (more frequent in young children). Pain in the neck or the back or both occurs more often in older children and young adults and most frequently in those who develop objective signs of nuchal and spinal rigidity. Diarrhea, coryza and cough were not encountered in any of the patients A biphasic course, in which about 2 days of fever and illness are followed by a symptom-free and afebrile period of about 2 days and then by a return of fever and more severe symptoms was seen in about 25 per cent of the cases. A few patients exhibited a triphasic course. The temperature is usually continuously elevated or intermittent for from 2 to 15 days, the median number being 6. The pulse was either normal or only slightly elevated.

On physical examination the majority of patients exhibited a red throat; and slightly enlarged cervical lymph nodes, either nontender or only slightly tender, were found in about 40 per cent. No enlargement of the postauricular or the suboccipital lymph nodes

was encountered The spleen was not palpable in any of the patients studied in Milwaukee or Cincinnati (Sabin et al, 1958a), while 33 per cent exhibited moderate enlargement during the Italian epidemic (Archetti et al, 1956) The liver extended 1 to 2 cm below the costal margin in about 4 per cent of the Milwaukee patients.

In the extensive Milwaukee epidemic of 1957 the incidence of rash decreased progressively with age Considering only virologically proved hospitalized and nonhospitalized cases a rash was seen in almost all children under 3 years of age, in about 70 per cent under 4 years, in 44 per cent of the 5- to 15-year group, and in only 7 per cent of those over 15 years of age In a detailed study of 43 cases, the rash appeared early after onset or within a few days after onset during the febrile period of the illness. It appeared generally first on the face or the face and the neck and within the ensuing 6 to 12 hours frequently spread to other parts of the body In 56 per cent of the cases the rash was present on the face, the neck, the trunk and the extremities, in 25 per cent only on the face, in 11 per cent on the face and the neck, and in 8 per cent on the face, the neck and the chest The rash is macular or maculopapular, faint pink to deep pink in color, and blanches on pressure The lesions are nearly always discrete, 1 to 3 mm in diameter, and only occasionally morbilliform, i e, confluent, with lesions up to 1 5 cm in diameter, usually on the face and the chest The rash persists for a day or less in some patients and for as long as 9 days in others, the median being 4 to 5 days The rash becomes pinkish-tan in color with the passage of time and does not desquamate A diffuse petechial rash, resembling that in meningococcemia, was observed in 3 patients during the Canadian outbreak (Laforest et al, 1957), although it was not stated that infection with ECHO 9 virus was specifically established in these 3 patients A petechial rash was also seen in one virologically proved case in Milwaukee.

An enanthem, with unilateral lesions occasionally resembling Koplik spots, was frequently present at the time of the exanthem, although in one large family infected with ECHO 9, only enanthem was found in 4 persons Conjunctivitis was present in 14 per cent of 76 virologically proved hospitalized patients

Patients were hospitalized, as a rule, because of nuchal or spinal rigidity or of marked pain in the neck or the back or both Actually, on physical examination only about 50 per cent of children under 10 years of age and about 65 per cent of those aged 10 to 40 years exhibited nuchal rigidity in the presence of a distinct pleocytosis of 10 cells or more Virus has been recovered from the cerebrospinal fluid of several patients who had only 5 cells per cu. mm and from that of patients without obvious nuchal rigidity with as many as 800 cells per cu mm (Sabin et al, 1958a). Spasm of the trapezius and other posterior cervical muscles when the chin touches the chest (Sabin's sign) may be detected in patients with pleocytosis in the absence of clear-cut nuchal or spinal rigidity, and it is clear that involvement of the central nervous system is much more frequent than suggested by the usual physical and laboratory criteria of meningeal irritation An epidemiologic and virologic survey in Milwaukee indicated that not less than 175 and probably as many as 300 ECHO 9 illnesses were at home for every ECHO 9 patient who was hospitalized because of suspected involvement of the central nervous system Since neck pain was encountered in 23 per cent of the patients under 10 and in 70 per cent of those over 10 who remained at home, it is probable that involvement of the central nervous system with few if any of the usual objective signs of meningeal irritation may be very common in ECHO 9 disease

A positive Kernig sign was noted in 9, a positive Brudzinski sign in 6, and a positive Babinski sign in only 3 of 76 hospitalized virologically proved cases These signs were noted only in children and were only transiently present Signs indicative of more extensive involvement of the central nervous system were observed in 5 virologically proved cases in the Milwaukee epidemic (Sabin et al, 1958a) Choreiform, jerking and undirected random movements of all extremities, right facial weakness and general facial grimacing were transiently present in a 1-month-old baby Coma and choreiform movements were noted in a 10-year-old girl. Loss of balance associated with an ataxic gait and tend-

and lymphocytes later on. The concentrations of sugar and protein in the cerebrospinal fluid were either within normal limits or slightly elevated

ECHO 9. The first strains of this type, originally designated as HE (human enteric) type 3, were recovered from healthy children during epidemiologically quiescent periods in Cincinnati and Mexico and represented only a small proportion of the large number of enteroviruses that were isolated (Ramos-Alvarez and Sabin, 1954, Ramos-Alvarez and Sabin, 1956) At the end of 1955 when this type of virus was renamed ECHO 9 there was only a single strain from a case of aseptic meningitis in West Virginia, and the importance of this virus as a cause of large epidemics of aseptic meningitis and febrile illnesses with rash did not become apparent until hundreds of strains recovered from patients in Belgium, Holland, Britain, Germany and Sweden in 1956 were almost simultaneously reported as being serologically similar to ECHO 9 (Nihoul and Quersin-Thiry, 1957, Johnsson, 1957, Sauthoff and Mittelstrass, 1957, McLean and Melnick, 1957, Boissard et al, 1957) ECHO 9 was subsequently also identified as the predominant virus in 1956 in epidemics in Switzerland (Baumann et al, 1957), Denmark (Godtfredsen and von Magnus, 1957) and Canada (Laforest et al, 1957). Viruses recovered from small outbreaks in Britain in 1954 and 1955 (Boissard et al, 1957) as well as those recovered only by tissue culture methods (Archetti et al, 1956) from the extensive outbreak in Italy in 1955 that was reported under the name of "Meningonevrassite Coxsackiosica Marchigiana" (Russi and Fua, 1956) have also been identified as related to ECHO 9 (Dalldorf, 1957b) In Germany other investigators reported the same disease either as being due to a new type of virus that was not pathogenic for mice (Hennessen, 1956) or as "Coxsackie Meningitis" (Brohl et al, 1957) because after several passages in tissue culture the viruses were pathogenic for mice as previously described In 1957 extensive epidemics of ECHO 9 disease affecting tens of thousands of people were studied in the U S A. (Sabin et al., 1958a)

The spectrum of the clinical manifestations of ECHO 9 disease, based only on virologically proved cases, definitely includes the aseptic meningitis syndrome and an undifferentiated febrile illness with or without exanthem and enanthem, and occasionally more extensive involvement of the central nervous system. The occurrence of exanthem which was a frequent finding in most of the European and American epidemics was not observed in the extensive Italian outbreak of 1955 (Archetti et al., 1956) or in the epidemic in a Swiss village in 1956 (Baumann et al, 1957), and it is possible that the incidence and the kind of clinical manifestations may vary with different strains of the virus.

The usual incubation period has been estimated at 5 to 8 days, but there is suggestive evidence that occasionally it may be as long as 15 to 20 days The onset was invariably with headache, usually severe and frontal, generalized malaise, irritability and weakness Fever (101° to 103° F.) appeared usually simultaneously with these symptoms or was delayed for 1 or 2 days, although patients who are not conscious of having fever may exhibit elevated temperatures Moderate chills were observed in 15 per cent of patients Other symptoms include sore throat (about 50%), nausea and vomiting and occasionally generalized abdominal pain (more frequent in young children) Pain in the neck or the back or both occurs more often in older children and young adults and most frequently in those who develop objective signs of nuchal and spinal rigidity Diarrhea, coryza and cough were not encountered in any of the patients A biphasic course, in which about 2 days of fever and illness are followed by a symptom-free and afebrile period of about 2 days and then by a return of fever and more severe symptoms was seen in about 25 per cent of the cases A few patients exhibited a triphasic course. The temperature is usually continuously elevated or intermittent for from 2 to 15 days, the median number being 6. The pulse was either normal or only slightly elevated.

On physical examination the majority of patients exhibited a red throat; and slightly enlarged cervical lymph nodes, either nontender or only slightly tender, were found in about 40 per cent. No enlargement of the postauricular or the suboccipital lymph nodes

riant of ECHO 10 virus Human beings were shown to have an increasing incidence of antibody for this virus with increasing age, and the tissue culture passaged virus reproduced typical coryza in chimpanzees (Sabin, 1957a)

ECHO 16 Viruses recovered in 1951 in Massachusetts independently from 8 patients with a diagnosis of nonparalytic poliomyelitis (Kibrick et al, 1957) and from 7 of 18 persons with a febrile illness and rash (Neva et al, 1954) were subsequently classified as ECHO 16 (Committee on Enteroviruses, 1957). Another small outbreak of 24 cases of so-called "Boston Exanthem" disease, caused by the same virus, was identified in a Pittsburgh suburb in 1954 (Neva, 1956) The aseptic meningitis syndrome, as observed in virologically proved cases in Boston in 1951, was not associated with rash and was characterized by relatively abrupt onset, low-grade fever (100° to 101 8° F), severe, usually frontal headache, sore or red throat, vomiting, and moderate nuchal and spinal rigidity The CSF pleocytosis was usually less than 50 predominantly mononuclear cells and not more than 100 per cu mm , and the protein and the sugar were normal Recovery was rapid and without sequelae except in one 17-year-old boy who developed persistent spasm of the muscles of the back with only gradual improvement over the period of a year (Kibrick et al , 1957)

The striking feature about the febrile exanthem is that the rash usually did not appear for several hours to 2 days after the temperature returned to normal and the other signs disappeared The incubation period, based on histories of limited contact, has been established at 4 to 5 days The onset is more or less abrupt with mild sore throat, "stomachache," headache and occasionally reddened eyes Low-grade fever (100° to 103° F) is usually present and lasts only 1 or 2 days This is followed by a pink or salmon-colored, usually discrete macular or maculopapular eruption The lesions vary in size from a few mm to 1 cm and are usually distributed mostly on the face, the chest and the back; occasionally, the rash is more extensive, involving also the buttocks and the extremities, including the soles of the feet There is no pruritis The rash lasts only 2 to 4 days An enanthem, consisting of single or multiple, raised reddened areas or of tiny, yellowish-white, raised lesions, or both, on the soft palate, the fauces, or the uvula, was seen in nearly 50 per cent of the Pittsburgh patients, while herpanginalike lesions observed in a few of the Boston patients appear to have been associated with concomitant Coxsackie A infections Adenopathy was absent or not pronounced. Both children and adults were affected, and the disease tended to be more severe and rash less prominent in the adults. Although multiple cases of the exanthem disease occurred in a family, there were also instances of the febrile illness without rash, and, especially in infants, rash with very slight or negligible preceding elevation of temperature Both outbreaks occurred during the summertime Recovery was rapid, and none of the patients required hospitalization

ECHO 18. This virus was first encountered in an 8-month-old baby with a diarrheal disease during the summer of 1955 in Cincinnati (reported as the D 3 strain—Ramos-Alvarez, 1957). It was the only strain among 24 cytopathogenic agents recovered from 56 children with diarrhea in 1955, and it was not found at all among 41 cytopathogenic agents recovered from 97 children with diarrhea during the summer of 1956 in Cincinnati (Ramos-Alvarez and Sabin, 1958), but it proved to be the sole cause of an outbreak of diarrhea in a nursery for premature infants and in a ward for older full-term infants in the same hospital during the summer of 1956 in New York (Eichenwald et al , 1958). Twelve of the 21 premature infants, aged 6 to 46 days, and 5 babies, aged 1 week to 2 months, were affected. There was neither fever nor hypothermia The diarrhea, consisting of 5 to 6 fairly large, watery, greenish stools per day, persisted for 1 to 5 days with a mean of 3 days Neither mucus nor pus cells were present, but in 2 infants small flecks of bright blood were noted on a single occasion Physical examination of the 12 prematures was unremarkable except for moderate abdominal distention in 2 and a listless and lethargic appearance in 6 others The signs and symptoms were similar but somewhat more severe in the 5 full-term babies The same virus was recovered from 15 of the 17 sick children but from none of the children without illness on the same wards

ency to fall to the right appeared 2 days after onset and persisted for 10 days in a 22-month-old baby A clinical diagnosis of mild bulbar poliomyelitis was recorded on a 9-year-old boy who had received 3 doses of Salk poliomyelitis vaccine and exhibited a transitory nasal voice with diminished gag and cough reflexes. A diagnosis of spinal paralytic poliomyelitis was recorded on a 20-year-old girl who had received 2 doses of Salk vaccine and exhibited weakness and dizziness on standing, was unable to do sit-ups, and had enough tightness of the back muscles and weakness of the hips to require crutches for getting about for a period of about 2 months. In the last 2 patients no poliovirus could be detected in the stools tested in the presence of ECHO 9 antiserum.

Seventy virologically proved patients in Milwaukee were examined by experienced physiotherapists after defervescence prior to discharge from the hospital, varying degrees of spasm of the erector muscles of the neck were noted in 54 (severe in only 3) and some spasm of the thoracic or lumbar erector muscles in 48 (severe in 9) with frequent tightness of the hamstring muscles None exhibited flaccid paralysis, authough weakness of the abdominal muscles was noted in some of the patients who had severe spasm of the erector spinal muscles Where severe spasm was present there was a tendency for it to persist for many weeks

The occurrence of ECHO 9 virus in a few patients with mild transitory paralysis, in whom concomitant infection with poliovirus was excluded by serologic tests, was mentioned in a report from Switzerland (Baumann et al., 1957) The occurrence of more severe encephalitic and paralytic manifestations, including 3 deaths in old patients recorded during the 1955 epidemic in Italy (Archetti et al., 1956, Russi and Fua, 1956), was not confirmed by isolation of virus, and 68 per cent of 19 such patients tested were serologically negative However, during the 1956 epidemic in Holland, ECHO 9 virus was recovered in a concentration of about $10^{6.5}$ TCD_{50} per Gm. from the medulla of an 8-month-old infant who died within 24 hours after onset of an illness characterized by fever and coma (Verlinde, 1957).

CLINICAL LABORATORY FINDINGS. The cerebrospinal fluid (CSF) is as a rule under increased pressure and exhibits a pleocytosis which in certain epidemics has been reported as high as 6,000 (Archetti et al, 1956) or 8,448 cells per cu mm. (Baumann et al, 1957). In the majority of virologically proved Milwaukee patients (64/76) the CSF contained less than 1,000 cells; in 9 of 76 the number of cells was between 1,000 and 2,000, and in 3 it was over 2,000. Within 24 hours after onset the percentage of polymorphonuclear cells varied from 15 to 98, while subsequently 85 per cent or more of the cells were usually lymphocytes The pleocytosis has been noted to persist for at least 3 to 4 weeks without any increase in the amount of protein (Baumann et al, 1957). The CSF protein is usually within normal limits and only occasionally in the range of 75 to 120 mg per 100 ml. The CSF sugar is usually between 50 and 70 mg per 100 ml. In the peripheral blood the number of leukocytes is usually diminished or normal and only rarely increased The blood sedimentation rate has been found to be increased in the majority of patients during the acute phase (Archetti et al, 1956; Baumann et al, 1957; Sabin et al, 1958a). Nearly 50 per cent of the virologically proved Milwaukee patients exhibited a slight microscopic hematuria, and only 10 per cent had a low-grade proteinuria, both of which were transient During the Italian epidemic (Archetti et al, 1956) 16 per cent had a positive cephalin-cholesterol flocculation reaction, and 6 per cent exhibited urobilinuria, and a mild degree of azotemia was attributed to the increased CSF pressure rather than to renal insufficiency.

ECHO 10. The precise clinical picture produced by the many antigenic variants of this virus cannot as yet be defined. However, it has been shown to be associated with a family outbreak of "steatorrheic enteritis" in which 1 adult and 2 children (aged 4 and 6) exhibited varying degrees of fever, lower abdominal pain and frequent greasy (in one instance yellowish white) stools containing up to 50 per cent of fat on a dry weight basis A winter epidemic of typical coryza among chimpanzees, housed for several months in a Cincinnati laboratory, has been found to be etiologically associated with an antigenic va-

ated with a febrile illness characterized by rhinorrhea, sneezing, coughing, "discharge" from the eyes, vomiting and loose, malodorous stools (Rosen et al, 1958) Prototype strains of newly established ECHO types 21 and 22-24 were isolated from patients with aseptic meningitis and diarrhea, respectively

PATHOLOGIC PICTURE

The pathologic picture produced by ECHO viruses in human beings is still unknown While the report that ECHO type 2 was the only demonstrable virus in the CNS of a fatal case described as clinically and histologically typical of bulborespiratory poliomyelitis (Steigman et al, 1953, Steigman, 1957) must at present be interpreted with caution, nevertheless it suggests the need for further studies along this line, especially in the light of Verlinde's (1957) demonstration of a very high concentration of ECHO 9 virus in the medulla of another fatal case

Various types of lesions have been observed in the CNS of monkeys inoculated intraspinally or intracerebrally with certain types of ECHO virus In some instances (ECHO 7 and 8) these consisted mostly of focal interstitial infiltration in the gray matter of the medulla and the midbrain (Ramos-Alvarez and Sabin, 1954), in others (ECHO type 17) of localized areas of neuronal destruction and infiltration in the spinal cord comparable with those seen with attenuated strains of poliovirus, and in the case of ECHO 10 destructive lesions affecting especially the ependymal lining of the ventricles and the choroid plexus (Sabin, unpublished observations)

ECHO-9 virus has produced mild lesions in the spinal cord of monkeys inoculated directly into the lumbar area The lesions, including cellular infiltration and neuronophagia, were limited to the lumbar area of the spinal cord but were present outside the area of traumatic injury produced by the injection (Benyesh and Melnick, unpublished observations) Virus was recovered from the spinal cords of a number of monkeys for at least a week after inoculation of ECHO-9 virus Even more significant are the lesions in the CNS of occasional monkeys inoculated intramuscularly with ECHO types 1, 2, 3, 4, 6, 10 and 13 (Wenner and Chin, 1957) The lesions were focal, present most often in the lumbar and the cervical segments of the spinal cord, and were characterized by neuronal degeneration, ranging from moderate damage to complete absence of neurons, glial proliferation and infiltration of the gray matter with mononuclear cells In the ECHO 10 group, hyperplasia of the choroidal epithelium with infiltration by mononuclear cells and round cell infiltration of subependymal tissues were especially pronounced

EXPERIMENTAL INFECTION, HOST RANGE

For inclusion in the ECHO group prototype strains are tested in newborn mice, rabbits and monkeys, and none has produced clinically manifest disease in the numbers of animals usually used in such tests Since different strains of the same type or specially selected variants of a single strain may exhibit different properties, as was discussed for ECHO 9 and 10 earlier in this chapter, the full potentialities of the various types of ECHO virus still remain to be explored Clinically inapparent infections are probably not infrequent in monkeys, as was suggested by the occurrence of CNS lesions

Only inapparent infections resulted when 2 chimpanzees were fed 10^9 TCD_{50} of ECHO 6 and $2\frac{1}{2}$ months later $10^{7.8}$ TCD_{50} of ECHO 4 (Itoh and Melnick, 1957) Virus was recovered from the throat and the stools for a period of 10 to 12 days, and in 1 chimpanzee the type 4 virus was found in the throat for 35 days No virus was found in the blood, and both neutralizing and complement-fixing antibodies appeared as a result of the infection After parenteral injection of $10^{7.8}$ TCD_{50} of ECHO 6 into 2 nonimmune and 1 spontaneously immune chimpanzee, a transient, low-grade viremia was detected 2 days after inoculation in one of the chimpanzees, but no virus was found in the throat or the stools After parenteral injection of $10^{6.2}$ TCD_{50} of ECHO 4 virus in 2 chimpanzees, viremia was found only 24 hours after inoculation in one, in the stools of only one on the 2nd and the 3rd days and in the throat of the other only on the 4th day Inapparent infections were also demonstrated in single chimpanzees following the feeding of ECHO 2 and 3 viruses

A typical "common cold" coryzal syndrome was produced by nasal installation of the tissue culture passaged "chimpanzee-rhinitis"

All of the sick children developed antibody for this virus, but no antibody was found in the others While there was thus no evidence of inapparent infection in the infants, 2 of the nurses in the premature nursery were found to be healthy carriers, and one of these nurses was also implicated in the outbreak on the infant ward

Although the illness was not severe in these infants, ECHO 18 virus was recovered from the stool of a 5-month-old baby who died in Milwaukee during the summer of 1957 after an illness of 6 days' duration characterized by fever, repeated vomiting of bloody or coffee-ground material, slight enlargement of the liver and coma of 4 days' duration There were only 4 cells in the CSF, and the blood leukocyte count was 27,200 with 61 per cent neutrophils There was no necropsy, and one cannot be certain that the ECHO 18 virus was the cause of death (Sabin et al., 1958a) However, it is remarkable that thus far ECHO 18 virus has been associated with illness only in infants under 1 year of age.

Role of ECHO Viruses in Summer Diarrhea of Infants and Children. Studies carried out in Cincinnati during the summers of 1955 and 1956 on diarrheal disease in 153 children under 4 years of age indicated that enteroviruses can be recovered from nearly 50 per cent when single rectal swabs are tested, and limited serologic tests showed that the incidence of infection with these viruses is considerably higher (Ramos-Alvarez, 1957, Ramos-Alvarez and Sabin, 1958) Of the 65 cytopathogenic strains, 63 per cent were ECHO viruses, a simultaneous study in 1956 on a control group of 100 children matched for age, residence, socioeconomic status, and time of sampling showed that the incidence of ECHO viruses was 6 times higher among the infants and the children with diarrheal disease than among those without diarrhea at the time of sampling The 41 ECHO viruses recovered in 1955 and 1956 were made up of 13 distinct types (II-1; VI-7, VII-11, VIII-3; X-1; XI-2; XII-3; XIV-5; XVIII-1; XIX-1, and 6 strains belonging to 3 new types). This finding would suggest that diarrheal disease may be a frequent manifestation of infection in early childhood with many different types of ECHO viruses. Since type 18 has turned up as the sole cause of an isolated outbreak among very young infants, it is not improbable that the other types may be found to play similar roles on other occasions Among 34 children with diarrheal disease from whom only viruses were recovered, 62 per cent exhibited fever and vomiting; 44 per cent had mucus, and 20 per cent blood in the stools, 29 per cent exhibited dehydration, and in 53 per cent the illness was severe enough to require hospitalization. Among 13 children from whom both viruses and pathogenic *E coli* were recovered, the clinical manifestations were about the same except that 92 per cent were markedly dehydrated and required hospitalization None of the children died Summer diarrheal disease of early childhood may be regarded as a syndrome of multiple etiology, much like the syndrome of aseptic meningitis, and when tests were carried out for pathogenic enteric bacteria as well as for enteroviruses a potential etiologic agent was found in at least 85 per cent of the cases (Ramos-Alvarez and Sabin, 1958).

Role of Other ECHO Viruses. ECHO types 1, 13, 15 and 17 have thus far not been associated with disease. ECHO types 2, 3 and 5 have been recovered sporadically from patients with aseptic meningitis—type 5 from the spinal fluid as well as from stools (Melnick, 1957). ECHO type 7 has been recovered from healthy children, with relatively higher frequency from infants and young children with summer diarrhea (Ramos-Alvarez and Sabin, 1958), and only infrequently from patients with the aseptic meningitis syndrome (Habel et al., 1957; von Zeipel and Svedmyr, 1957). The precise role of types 8, 11 and 12 still remains to be elucidated, although type 8 has been associated with a febrile illness exhibiting clinical manifestations referable to both the respiratory and the alimentary tracts (Rosen et al., 1958). ECHO type 14 has been recovered sporadically from patients with aseptic meningitis, in one case from the spinal fluid (Melnick, 1957; Meyer et al, 1957; Ormsbee and Bell, 1957), in one instance associated with rash (Sabin et al., 1958), and from infants with summer diarrhea (Ramos-Alvarez and Sabin, 1958) ECHO type 20, represented by 100 strains recovered from young children in an orphanage in Washington, D. C., has been associ-

was little or no loss in activity after storage at 4° C. for 18 to 28 days for types 7, 8 and 11, while types 9 and 10 gradually lost activity This variation was more marked at room temperature (22° to 25° C), and with concentrations in the range of 100 TCD_{50}, virus was not detected at the end of 24 hours with types 7, 9 and 10, but types 8 and 11 persisted for more than a week While 90 per cent of the prototype ECHO 9 virus was lost in 3 days when approximately 100 TCD_{50} were stored at 4° C , stool extracts containing $10^{2.7}$ to $10^{3.4}$ TCD_{50} of 3 epidemic strains of ECHO 9 virus exhibited no loss in titer on storage at 4° C for 7 days (Eggers and Sabin, unpublished studies) A 50 to 90 per cent drop in titer was observed at the end of 24 hours at 37° C with ECHO types 6 and 7 and poliovirus type 1, while 99 9 per cent of Coxsackie A 9 was inactivated under the same conditions (Itoh, unpublished studies)

To avoid the accumulation of large amounts of heat-inactivated virus, which might yield misleading results in neutralization tests or interference phenomena with poor yields of virus in the case of slow-growing viruses, it is advisable to harvest tissue culture fluids as soon as most or all of the cells exhibit a cytopathogenic effect This is particularly important with such slow-growing and temperature-sensitive viruses as ECHO 10, 16 and 19 All specimens for isolation of ECHO virus should be stored at −20° C or lower temperatures as soon as possible after they are obtained from the patient Tissue culture fluids of all ECHO viruses can be shipped without refrigeration, but temperature-sensitive types (e g , 10, 16, 19) may need to be submitted to several rapid passages before maximal and optimum titers are obtained

ECHO viruses are not inhibited by the common antibiotics, i e , penicillin, streptomycin, tetracycline or mycostatin

Tissue cultures derived from the kidneys of rhesus and cynomolgus monkeys provide the cells of choice for the isolation and the optimum propagation of the ECHO viruses The cells derived from certain African species (Table 21), especially the green monkeys, *Cercopithecus aethiops sabaeus* (Drouhet, 1955), are as good or better for the

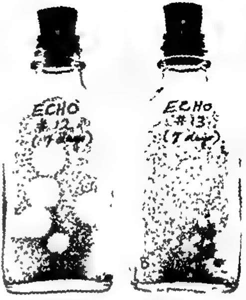

Fig 94 Plaques in monkey kidney monolayer cultures under agar, produced by ECHO 12 and ECHO 13 viruses, 7 days after seeding Plaques of ECHO 12 resemble those of wild strains of poliovirus (Hsiung, G D , and Melnick, J L , 1958, Orphan viruses of man and animals, Ann New York Acad Sc , *70*, 342-360)

types tested thus far, while those of the African red grass monkey (*Erythrocebus patas*) have been found satisfactory for ECHO types 7, 8 and 12, as well as for the Coxsackie B and polioviruses, and practically useless for ECHO types 1 to 6, 9, 11, 13 and 14, as well as for Coxsackie A 9 (Hsiung and Melnick, 1957b)

Cultures of human embryonic skin and muscle, postnatal uterus, or kidney tissue have been used for certain ECHO viruses (Kibrick et al , 1957) HeLa cells are unsuitable for the primary isolation of ECHO viruses, but after initial outgrowth and enrichment of the viral population it has been possible to adapt most of these viruses to growth in HeLa cells (Ramos-Alvarez and Sabin, 1956, Archetti et al , 1957, von Zeipel and Svedmyr, 1957, Ormsbee and Melnick, 1957) This selection of variants, possessing pathogenicity for HeLa cells, com-

virus (antigenic relative of ECHO 10) in 4 of 6 chimpanzees without preinoculation antibody. The virus was recovered from the nasal secretions and, in even greater concentration, from the stools of all 6 chimpanzees for as long as 10 to 14 days, and all developed neutralizing antibodies (Sabin and Schwarz, unpublished data)

ETIOLOGY

The extent to which the different types of virus now included in the ECHO group may vary in size is as yet unknown, because only 8 of the 24 established types have been measured Types 1, 2 and 3 (Melnick et al, 1953) only partly passed gradocol membranes of 38 mμ and were completely held back by membranes with an average pore diameter of 30 mμ Types 8, 9 and 11 passed 41 mμ membranes and were completely held back by the 27 mμ membranes, while the type 7 virus also passed the 27 to 29 mμ membranes, although only in minimal amounts (Ramos-Alvarez, unpublished data, Benyesh et al, 1958). On the basis of the Elford formula, which yields estimates that are smaller than those obtained by electron-microscopy, the above 7 viruses would have a size in the range of 10 to 15 mμ, i e, of the same order of magnitude (12 to 18 mμ) found by similar methods of measurement and estimation of size for the 3 types of poliovirus (Sabin et al., 1954). By similar methods, however, 3 different strains of ECHO 10 were found to have an estimated size of 60 to 90 mμ (Sabin, 1957). If a factor of 0 64 is used to convert limiting pore diameter, i e, that which just allows virus to pass, to particle size, the diameters obtained are in agreement with electronmicroscopic studies of those viruses obtained in crystalline arrays or of freeze-dried particles (Black, 1958). Application of this factor to the ECHO viruses studied, as well as to poliovirus, yielded particle diameters of 24 mμ (Benyesh et al, 1958)

Estimates of size based on the rate of inactivation by high energy electrons, alpha particles and deuterons yielded a value of 28 to 30 mμ for the infective unit and approximately 10 mμ for the complement-fixing antigenic unit for ECHO types 1 and 7, as well as for the 3 types of poliovirus (Benyesh et al, 1958)

Most ECHO viruses are relatively stable, so infected tissue culture fluids can be maintained at −20° C. for long periods of time without significant changes in titer. An exception to this rule is type 19, which is best preserved at −70° C The stability at 4° C and higher temperatures varies for different types and also for different strains of the same type. Tests on the prototype strains of types 7 to 11 (Ramos-Alvarez, unpublished studies) showed that at high concentrations of virus (10^5 to 10^7 TCD_{50} per ml.) there

6', certain strains of 8, 9, 11, 13, 14, 15, 16, 17, 18, 19) are irregular in shape and often small with diffuse boundaries (Figs 94 and 95) However, it has been found that different strains of the same type may produce different kinds of plaques, thus while the prototype, "Hill" strain of ECHO 9, produced only minute plaques (about 1 mm at 5 days), the "Vespa" strain derived from the 1955 epidemic in Italy yielded large plaques measuring about 11 mm at 5 days (Archetti, quoted by Wenner, 1957) In natural mixed infections small numbers of poliovirus particles may be isolated easily and quickly by passing progeny from the larger circular plaques (Fig 96)

FIG 96 Rhesus (*left*) and patas (*right*) cultures, 7 days after seeding with a stool specimen (D-11) from a patient experiencing a mixed viral infection On the rhesus culture, a single large poliovirus plaque (P) and 5 small ECHO plaques are present On the patas culture, only poliovirus plaques appear, because the cells are not susceptible to most ECHO viruses Progeny from the plaques were passed and typed in neutralization tests The large plaques yielded type 1 poliovirus, and the small plaques ECHO 17 virus (Hsiung, G D, and Melnick, J L, 1958, Orphan viruses of man and animals, Ann New York Acad Sc, *70*, 342-360)

Twenty different antigenic types (Table 22) have already been segregated from the huge mass of ECHO viruses, and many additional strains are in the process of classification (Committee on Enteroviruses, 1957) The different types were separated on the basis of cross-neutralization tests but similar results are also obtained by complement-fixation tests Cross-neutralization tests are necessary not only to guard against mixtures, which are also avoided by deriving the prototype strains from single clones (progeny obtained by plaque passage or from serial terminal dilutions), but also because of the not infrequent occurrence of so-called "prime" strains Such strains are neutralized to very low titer or not at all by the existing prototype antiserum, while an antiserum against the "prime" strain neutralizes the prototype virus to about the same titer as itself (Table 23) Naturally occurring strains with "prime" or other variations in antigenic relationship to the prototype strains are now known for types 5, 6, 7, 9, 10, 11 and 13 Varying degrees of antigenic interrelationship both by neutralization and CF tests have been found only for types 1, 8, 12 and 13 There is no common CF antigen for the ECHO group The possibility that some of the ECHO viruses may share a common antigen with the polioviruses requires further study with human sera, since it has been reported that persons without neutralizing antibodies for any of the 3 types of poliovirus developed CF antibodies for heat-inactivated poliovirus antigens after infection with ECHO 6 (von Zeipel and Svedmyr, 1957), or during a summer period when the antigenic stimulus was unknown (Melnick, 1955b)

Neutralizing antibodies are commonly determined by measuring the dilution of serum capable of preventing or markedly delaying the cytopathic effect of approximately 100 TCD_{50} of virus in tube cultures (Committee on the Enteroviruses, 1957) The metabolic inhibition test in panel cups under oil (Melnick and Opton, 1956) has also been used with certain strains The plaque reduction method has been especially useful with ECHO 4 virus, for which antibody is demonstrable

parable with the selection of mouse pathogenic variants in the case of ECHO 9 and 10, has not been achieved with ECHO 4 or all strains of the same type of virus, e.g., ECHO 9 (von Zeipel and Svedmyr, 1957; Archetti et al, 1957; Archetti, quoted by Wenner, 1957) Although fibroblastic cultures from human embryonic lung have been found suitable for primary isolation of many ECHO viruses (von Zeipel and Svedmyr, 1957), they were not suitable for certain epidemic ECHO 9 strains (Quersin-Thiry et al., 1957) Human amnion cells yielded satisfactory results with some ECHO 9 strains (McLean and Melnick, 1957, Quersin-Thiry et al., 1957) but completely failed to detect other ECHO 9 strains (Faulkner et al, 1957) and the ECHO 18 strains that were present in the stools of infants with diarrhea (Eichenwald et al., 1958), they were also only partly affected by ECHO 16 virus (Neva and Zuffante, 1957) The ECHO 16 virus has little or no effect on human kidney cells, and rhesus testicular cells are more sensitive than rhesus kidney cells

The ECHO 9 strains encountered in the 1956 epidemic in Belgium were reported (Quersin-Thiry et al., 1957) as being without effect on the following cell lines. HeLa, two strains of human kidney epithelium (adult and fetal), human lung fibroblasts, strain KB, conjunctiva, human intestine, human liver, mouse mammary carcinoma cells, and normal mouse kidney epithelium Pig kidney tissue cultures, which were found to be susceptible to all the Coxsackie B and adenoviruses, were not susceptible to ECHO types 1 to 9, 11, and 14 to 19 inclusive as well as to the Coxsackie A and polioviruses, ECHO 10 produced "some degree" of cytopathic effect (Guerin and Guerin, 1957)

ECHO types 2, 5, 10, and certain strains of types 3 and 6, have failed to produce plaques in rhesus or cynomolgus kidney tissue cultures under agar Types 7, 12, and certain strains of 8 produce large circular plaques with clear centers and sharp boundaries, similar to those of wild strains of polioviruses, on both rhesus and patas cells (Hsiung and Melnick, 1957a) The plaques of other ECHO viruses (1, 3, 4,

FIG. 95 Plaques of most ECHO viruses develop slowly. Those of ECHO 3, 4, 6, and 9 shown were photographed 11 days after seeding (Hsiung, G D, and Melnick, J. L, 1958, Orphan viruses of man and animals, Ann. New York Acad Sc., 70, 342-360)

ECHO 3, 6, 7, 10, 11 and 12 (as well as Coxsackie B 3) but not in those of ECHO 1, 2, 5, 8, 9, 13, 14 or in those of poliovirus types 1, 2, 3 or Coxsackie A 9 (Goldfield et al, 1957) ECHO 4 and the other Coxsackie B viruses have exhibited only slight hemagglutinating activity. The hemagglutinating property has been shown to be a function of the virus particle The hemagglutinin combines with the erythrocytes and can be eluted from them with exhaustion of the receptors for the same virus and to a certain degree also for the other viruses of the group (the receptor gradient being roughly in the order of ECHO 6, Coxsackie B 3, ECHO 3, 11, 7, 12 and 10), but not for influenza virus Treatment of Group O erythrocytes with receptor-destroying enzyme or influenza B virus (Lee) did not decrease their reactivity with the hemagglutinins of the enteroviruses Specific hemagglutination-inhibition antibody of high titer was demonstrated only in homotypic antisera, but the significance of the varying lower heterotypic titers cannot be evaluated until a method is found for removing the nonspecific inhibitors in various sera. These new findings on hemagglutinins seem to provide still another bridge between the ECHO and the Coxsackie viruses

DIAGNOSIS

Although there are no clues that might direct suspicion to ECHO viruses as a cause of disease in individual cases, the following epidemic situations during the summer and the autumn seasons may be regarded with suspicion:

1. A high incidence of the aseptic meningitis syndrome with few or no paralytic cases

2 Outbreaks of febrile illness associated with a high incidence of rash, especially in

* Types 21 to 24 have recently been added to this list

in only very low titers or not at all by the other methods (Itoh and Melnick, 1957) The culture fluids to be used for neutralization tests should be harvested early before heat-inactivated particles accumulate, because such inactivated virus may bind antibody and give low serum titers. The serum-virus mixtures are incubated for 1 hour at room temperature prior to addition to the culture tubes, and the amount of virus used in the test is checked by titrating the estimated 100 TCD_{50} after all the serum-virus mixtures have been added to the tubes.

Antigens for complement-fixation tests may be prepared from unheated monkey kidney tissue culture fluids (Melnick, 1955a, von Zeipel and Svedmyr, 1957, Hammon and Sather, unpublished observations). Potent antigens have been prepared in cultures maintained with C-E medium (0 01% cysteine, 0 25% glucose, Earle's salt solution) (Itoh and Melnick, 1957), but with the usual media these are often too anticomplementary to permit the use of an optimum amount of antigen Treatment with fluorocarbon has been recommended for removal of anticomplementary activity (Halonen, 1957), and more satisfactory and less anticomplementary antigens have been prepared from HeLa cells with adapted strains of virus (Archetti et al , 1957) Complement-fixation may be carried out by the micromethod on plates or by the conventional method in tubes.

Hemagglutinins of relatively high titer for human Group O erythrocytes have been reported in monkey kidney tissue cultures of

mon cells have been satisfactory for some but not all, and human kidney cells must be regarded as unsatisfactory for general use. After a cytopathogenic agent is recovered, a preliminary screening is carried out using a 10^{-4} dilution of culture fluid (titrating the virus simultaneously) and various pools of antisera against the 3 types of poliovirus, all available types of ECHO virus, and the cytopathogenic Coxsackie viruses (A 9 and B 1 to B 5). The final identification is made with individual antisera against 100 TCD_{50} of virus (Committee on Enteroviruses, 1957). In special cases in which it may be important to rule out or establish concurrent infection by 2 or more viruses, the original specimen is recultured in the presence of antiserum for one of the known or suspect viruses, and the acute and convalescent phase sera are tested for antibody against the suspected viruses. Tests on progeny from different types of plaques produced by the original specimens and inoculation of the original material into newborn mice are additional methods for detecting mixed infections.

TREATMENT

Treatment is symptomatic. Withdrawal of 15 to 20 ml of cerebrospinal fluid during the diagnostic lumbar puncture has been reported by several investigators (Archetti et al., 1956, Baumann et al., 1957) to relieve the very severe headache encountered in some patients with aseptic meningitis.

EPIDEMIOLOGY

The ECHO viruses are world-wide in distribution. They produce transitory infections of the human alimentary tract and are not comparable with the enteric bacteria which are constantly present in the intestinal tract. At least some of the viruses currently in the ECHO group (e.g., types 8, 10, 20) have been associated with clinical manifestations referable to the nasal mucosa. The incidence of ECHO viruses in the stools of healthy human beings, not in contact with acute febrile illnesses, has been shown to vary with age, season and socio-economic status. Tests on single rectal swabs from 1,566 healthy children during the summer of 1953 in Cincinnati indicated a carrier rate for ECHO viruses only of 5.2 per cent among those aged 1 to 4 years, 2.6 per cent in the 5 to 9 group, 0.2 per cent in the 10 to 14 group and none among 154 persons aged 15 to 17 (Ramos-Alvarez and Sabin, 1954). No ECHO viruses were recovered in repeated tests on stools of 100 men aged 20 to 30 years in Ohio (Sabin, 1957b). Using single rectal swabs for sampling, the incidence of nonpoliovirus cytopathogenic agents (more than 90% ECHO viruses) during late May and early June among 1,491 children aged 1 to 4 years in Mexico City was about 16 per cent (Ramos-Alvarez and Sabin, 1956). Repeated tests on the stools of 136 healthy, preschool children in Charleston, W. Va., over a 29-month period indicated that 90 per cent of the cytopathogenic enteroviruses were recovered during the summer and the autumn months and that the incidence was 3 to 6 times higher in the lower socio-economic district than in the middle-to-upper-middle-class districts; 52 per cent of these viruses belonged to the ECHO group (Honig et al., 1956). In areas further south such as Phoenix, Ariz. (Melnick, 1957) and Louisiana (Gelfand et al., 1957) the incidence of enteroviruses among healthy children was more evenly distributed throughout the year but still markedly higher during the months of May to October.

[illegible]

in an isolated community in Nova Scotia during the months of February and March (Faulkner et al., 1957). The size of the recorded outbreaks has varied from small groups to hundreds and many thousands, depending on the size of the community and the methods used for determining the incidence of infection with a specific ECHO virus. Epidemiologic surveys limited to hospi- [illegible]

studies are inadequate, since many enteroviruses are frequently being disseminated si- [illegible]

with only 27 reported cases of "nonparalytic

younger children, with or without a concomitant increase in the number of cases of aseptic meningitis

3 Outbreaks of diarrheal disease, especially in very young infants, from which few if any of the established enteropathogenic bacteria can be recovered.

Although thus far only the ECHO 4, 9 and 16 viruses have been associated with epidemics of febrile exanthem disease, sporadic febrile illnesses with rash have now been observed with infections caused by other ECHO (6, 14, and an as yet unclassified type) and Coxsackie (A 9 and B 4) viruses (Sabin et al, 1958b) and one cannot be certain that these or other members of the family of enteroviruses may not give rise to epidemics of exanthem disease at other times. The experience gained thus far may also provide the following clues regarding the viruses that may come under suspicion.

1 An outbreak in which the majority of the cases exhibit fever for not more than 2 days and the rash *follows* the fever by a day or two would suggest ECHO 16, while an outbreak characterized by fever of longer duration with rash appearing at the onset or during the febrile period would suggest ECHO 9 or some other agent

2 An outbreak of aseptic meningitis in which many patients exhibit a pleocytosis of 1,000 or more cells would suggest ECHO 9, even if rash were not a part of the clinical picture.

A specific virologic diagnosis is achieved most rapidly by isolation of virus from throat swabs, stools and cerebrospinal fluid, preferably all 3, when one is dealing with the aseptic meningitis syndrome Serologic tests, although useful for purposes of confirmation or under special conditions in individual cases, are impractical for rapid identification of the predominant viruses in an epidemic situation because the number of enteroviruses is too great. Properly obtained throat swabs (preferably 2 dry cotton swabs passed over the posterior pharyngeal wall and tonsillar fauces eluted in 2 to 4 ml. of tissue culture medium or Earle's solution containing 2,000 units of penicillin, 2 mg streptomycin and 250 units of mycostatin per ml) have proved to be an excellent source of virus in ECHO 9 (15 of 18 positive during first 3 days and 11 of 17 at 4 to 7 days—Sabin and Wigand, 1958; 29 of 41 during first 3 days—Archetti et al, 1956) and ECHO [illegible] infections (49 of 84 positive—Karzon, 1957a). Virus has been recovered from the throat in ECHO 4 and ECHO 16 infections, but the number of patients studied was too small to provide an indication of incidence. In the ECHO 18 outbreak, however, the virus could not be recovered from the throat of any of the infected infants or adult carriers The stools should be obtained for virus isolation whenever possible, but rectal swabs obtained in the same kind of medium as the throat swabs and requiring no preparation for inoculation in tissue cultures, can in many instances provide the most rapid means for identifying the predominating viruses The incidence of virus recovery from the stools of virologically proved cases (i e., by serology or isolation from other sources) has been approximately 85 per cent during the first week in patients with ECHO 6 and 9 infections and even higher in those with ECHO 16 and 18 infections The highest incidence of virus recovery from the cerebrospinal fluid has been in ECHO 9 infections (40 of 51 virologically proved cases—Sabin et al, 1958a, 47 of 90 tested during first week—Archetti et al., 1956); 7 strains of ECHO 6 have also been isolated from the CSF but the number tested was not indicated (Karzon, 1957). In addition, ECHO 5 and 14 viruses have each been recovered from the CSF (Melnick, 1957). The virus is only rarely present in the blood after onset of illness ECHO 9 virus was recovered from the serum of one contact tested 36 hours before onset of illness, from 1 of 6 patients tested within 24 hours after onset, and from none of 22 tested 2 to 6 days after onset (Sabin and Wigand, 1958) ECHO 16 virus has been recovered once from the blood clot of a patient with fever 2 days after onset of illness but not from [illegible] other afebrile patients tested 2 to 5 days after onset (Neva and Zuffante, 1957).

As was pointed out in a previous section, tissue cultures derived from the kidneys of rhesus or cynomolgus, and perhaps also green African, monkeys provide the cells of choice for isolation of most ECHO viruses Fibroblastic cultures from human embryonic lung have yielded good results, while human am-

in the stools of patients during the first week after onset was very small—less than 100 TCD_{50} per Gm in 65 per cent of 85 stools tested and usually only in the range of 10^2 to 10^3 TCD_{50} per Gm in the others The incidence of ECHO 9 virus in the stools of patients drops rapidly after the end of the second week—86 per cent (of 91) during the first week, 74 per cent (of 31) during the second week, 37 per cent (of 8) during the third and the fourth weeks, and only 5 per cent of 22, who were positive earlier, between the fifth and the seventh weeks—with only traces of virus being recovered in the stools obtained beyond the second week after onset (Sabin and Wigand, 1958)

CONTROL MEASURES

No specific control measures are available Until more [illegible] known about the effects of infection with various ECHO viruses on fetal development (Sabin et al, 1958a), it may be advisable for pregnant women, especially during the first trimester, to avoid all unnecessary intimate contact with children and adults exhibiting acute febrile illnesses, particularly those associated with rash, during the summer and the autumn months Avoidance of such contact may also be advisable for premature babies and very young infants During institutional outbreaks of viral, diarrheal disease among premature babies or infants, it may be helpful to identify possible carriers by testing the stools of the staff for cytopathogenic enteroviruses

Guerin, L F, and Guerin, M M, 1957, Susceptibility

poliomyelitis," a survey of 500 persons in 143 families revealed that 16 per cent of the population had a compatible illness, and 55 per cent of the ill persons in the nonhospitalized group exhibited fever, headache and stiff neck or back (Lehan et al, 1957). Although only 21 of 57 individuals tested during this outbreak (including mostly patients with aseptic meningitis, some with minor illness or familial associates without illness) yielded cytopathogenic viruses, all 21 excreted ECHO 4 virus, and in 4 instances together with poliovirus (Chin et al, 1957). The incidence of ECHO 4 infection in families without illness was not determined, but the occurrence of inapparent infection was established in familial associates.

During the epidemic of ECHO 9 disease in Milwaukee in 1957, it was established that infection with this virus was almost entirely limited to families exhibiting compatible illnesses (Sabin et al, 1958a). Among 26 noncontact families with compatible illnesses during 1 week in August at the peak of the epidemic, tests on the stools of 104 ill and well persons yielded 66 cytopathogenic enteroviruses of which 58 were ECHO 9 During the same week stool specimens were obtained from 107 members of 25 families without illness, of similar socio-economic status and residing in the same neighborhoods as the families with illness, among the 10 cytopathogenic agents recovered from the 107 stools only 1 was ECHO 9 During the same week a survey was made of 2,447 households containing 11,403 persons (about 1 5% of the total population of 740,000 in Milwaukee) and 62 households (including the 26 studied virologically) had one or more persons with compatible illnesses A crude estimate suggested that not less than 175 and probably as many as 300 people were ill with ECHO 9 disease for every one that was hospitalized During the course of the Milwaukee epidemic, extending from the end of June to the end of September (confirmed by isolation of ECHO 9 at both extremes) only 149 residents of the city were hospitalized, but actually the epidemic may have affected approximately 45,000 persons, i e, an estimated attack rate of only 6 per cent compared with the estimated attack rate of about 16 per cent for the epidemic of ECHO 4 disease in Marshalltown, Iowa Among the families with ECHO 9 infection, the rate of inapparent or unrecognized infection (based only on recovery of virus in the absence of recent, current or subsequent illness) was 18 per cent, while the rate of compatible illnesses was even higher (Sabin et al, 1958a).

The age incidence of disease observed during epidemics of ECHO 4, 6, 9 and 16 viruses indicates that all groups are attacked, apparently in proportion to the incidence of pre-existing immunity An exception to this rule is ECHO 18, which thus far has affected only infants under 1 year of age. An enterovirus antibody survey in Connecticut indicated that antibodies against ECHO viruses were not as prevalent as those against the polioviruses (Davis and Melnick, 1958). Among those under 15 years of age, the per cent positive for the ECHO types studied were: II—19, V—6, VI—17, IX—9, while among the adults the corresponding figures were II—36, V—16, VI—23 and IX—19. A preponderance of males among patients with aseptic meningitis in a ratio of about 2 5:1 has been observed in ECHO 6 (Karzon, 1958) and about 2:1 in ECHO 9 infections (Archetti et al., 1956, Baumann et al, 1957, Sabin et al, 1958a) Multiple cases in families, particularly in those with many young children, are the rule rather than the exception While secondary cases in families occur for the most part during the first week, longer intervals up to 15 and 20 days have also been observed Observations of families into which different enteroviruses were introduced under natural conditions demonstrated that ECHO 6, Coxsackie A9, B3, and poliovirus spread through the susceptibles with equal ease (Davis and Melnick, 1958) In the course of this study, confirmation was obtained of the effect of Salk vaccine in increasing the poliomyelitis antibody prevalence and decreasing the incidence of poliomyelitis in the vaccinated group In contrast, the vaccine had no effect on the prevalence of aseptic meningitis due to Coxsackie or ECHO viruses

Dissemination by fecal contamination appears to be the most important mode of spread for the epidemic ECHO viruses studied thus far Among 8 patients who had varying amounts (10^1 to $10^{5.2}$ TCD_{50} per swab) of ECHO 9 virus in their throats during the acute phase of their illness, none had demonstrable virus in swabs from the nose, and the only patient to yield any virus ($10^{1.8}$ TCD_{50} per swab) in swabs from the anterior buccal mucosa, tongue and gums was the one who had $10^{5.2}$ TCD_{50} per swab in the throat (Sabin and Wigand, 1958). The stools may be most infectious before onset of illness, e g, the amount of ECHO 9 virus found

in the stools of patients during the first week after onset was very small—less than 100 TCD_{50} per Gm in 65 per cent of 85 stools tested and usually only in the range of 10^2 to 10^3 TCD_{50} per Gm in the others The incidence of ECHO 9 virus in the stools of patients drops rapidly after the end of the second week—86 per cent (of 91) during the first week, 74 per cent (of 31) during the second week, 37 per cent (of 8) during the third and the fourth weeks, and only 5 per cent of 22, who were positive earlier, between the fifth and the seventh weeks—with only traces of virus being recovered in the stools obtained beyond the second week after onset (Sabin and Wigand, 1958)

CONTROL MEASURES

No specific control measures are available Until more is known about the effects of infection with various ECHO viruses on fetal development (Sabin et al, 1958a), it may be advisable for pregnant women, especially during the first trimester, to avoid all unnecessary intimate contact with children and adults exhibiting acute febrile illnesses, particularly those associated with rash, during the summer and the autumn months Avoidance of such contact may also be advisable for premature babies and very young infants During institutional outbreaks of viral, diarrheal disease among premature babies or infants, it may be helpful to identify possible carriers by testing the stools of the staff for cytopathogenic enteroviruses

Infectious Hepatitis and Serum Hepatitis

There are probably several viruses that cause hepatitis in man, and certain of them may be variants of one general group Two major members of this group, known as hepatitis virus A and virus B, are the causative agents of *infectious hepatitis* and *serum hepatitis*, respectively Synonyms for the former disease are *infective hepatitis* and *epidemic jaundice*, and for the latter, *homologous serum jaundice, syringe jaundice, postvaccinal hepatitis, transfusion jaundice*, etc. Presumably, *infectious hepatitis* is an example of the so-called "enteric group of infectious diseases" *Serum hepatitis*, on the other hand, has many features that do not belong in the enteric category and, epidemiologically speaking, are almost unique. Although there is scant knowledge concerning the exact relationship between these 2 viruses (A and B) or groups of viruses, some kind of distinction between them seems to be desirable The properties on which the differentiation is based are not well defined but can be discussed in terms of certain epidemiologic, immunologic and clinical aspects of the illnesses that virus A and virus B cause.

INFECTIOUS HEPATITIS

Introduction

Infectious hepatitis is a relatively common and widespread acute or subacute viral infection in which there is a diffuse involvement of the liver. It appears in both endemic and epidemic form Clinically, it is characterized in the early stage by fever, anorexia, nausea, vomiting and abdominal distress, with subsequent hepatomegaly and jaundice. In children the illness may be brief, but in adults it usually lasts 3 to 8 weeks It is thought to be spread by the oral-enteric route and, in general, to give rise to homologous immunity.

History

Infectious hepatitis has long been recognized in civilian and military medical history under a variety of different names. Its present-day prominence stems not only from its current frequency and occasional seriousness but also from the development of new concepts of pathogenesis and the significance attached to a new name. For, as long as *infectious hepatitis* went under such names as *epidemic jaundice* or *acute catarrhal jaundice* (both regarded as mild illnesses) or *acute yellow atrophy of the liver* (regarded as a rare although very serious disease), it occupied a place of little importance in medical thought This was its situation prior to 1940 *Now not only is it regarded as a common* virus disease with a name emphasizing the idea of contagion but also it carries the possibility of moderately serious implications in adults. Much of this new concept of its pathogenesis and severity arose when the idea gained credence that this type of jaundice was not due to obstruction of the common bile duct with a mucous plug but rather to a destructive lesion of the hepatic parenchyma. The degree to which this disease

proved to be a scourge to troops during World War II further magnified its importance

Prior to the 1880's, epidemic jaundice was often confused with Weil's disease. Originally differentiated from infectious hepatitis on clinical grounds in 1886, cases of leptospirosis have more recently been clearly diagnosed by immunologic tests Later pioneers in clarifying the identity of infectious hepatitis as a clinical entity include Quincke, 1903, and Cockayne, 1912 Blumer, 1923, was among the first in the United States to point out that infectious hepatitis probably represented the epidemic form of "catarrhal jaundice" Rich, 1930, again drew attention to the fact that at necropsy nearly all cases of "catarrhal jaundice" showed a diffuse hepatitis

Modern concepts of the viral etiology of hepatitis developed about 1939 when various observers (Findlay et al, 1939) in West Africa described cases of postvaccinal (yellow fever vaccine) hepatitis This is now commonly called serum hepatitis and, although its existence had been recognized since the 1880's and repeatedly described since then, Findlay et al (1939) were apparently the first to conclude that the causal agent was a virus In 1942, Voegt, in Germany, was the first to report the oral transmission of infectious hepatitis (virus A) from man to man by feeding duodenal contents from a patient suffering from this illness. Subsequently, others demonstrated the causative agent in the blood (Cameron, 1943) and the feces (MacCallum and Bradley, 1944, Havens et al, 1944, Neefe et al, 1946) and showed that it was capable of passing bacteria-tight filters and was transmissible serially in volunteers (Havens, 1945a). Nevertheless, this agent has not yet been "isolated" in the sense that it has been seen or cultured or definitely transmitted to laboratory animals, and its properties that are now known have been demonstrated entirely in volunteers

Clinical Picture

The incubation period ranges from 15 to 40 days, with an average of about 25 In childhood, the course of disease is shorter and milder than it is in adults (Horstmann et al., 1947), and in young infants it may be so mild

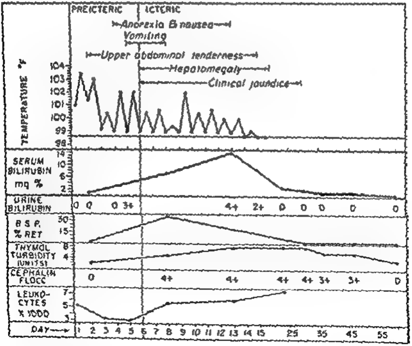

Fig. 97 The clinical course of infectious hepatitis in an experimentally infected volunteer

as to escape notice (Capps et al, 1950). In both children and adults, but particularly in *the former, jaundice may be absent or quite* fleeting Estimates of the ratio of nonicteric to icteric cases differ in various epidemics, but a conservative ratio in adults would be 1 1. The course of disease in adults is usually, and somewhat arbitrarily, separated into 2 phases: preicteric and icteric (see Fig. 97) Each *phase has characteristic symptoms, signs and* laboratory findings Actually, the great majority of patients with hepatitis are already in *the icteric phase by the time the diagnosis is* made, so that the clinical aspects of the second phase are more familiar to most physicians than are those of the first phase

The preicteric phase, which may range from 1 to 21 days, may start abruptly or insidiously with symptoms such as anorexia, nausea, moderate abdominal discomfort and diarrhea A large proportion of patients have fever at this time, often accompanied by chills or chilly sensations Posterior cervical lymphadenopathy ■ common (Barker et al, 1945), and splenomegaly may be present Although the liver is not usually enlarged in this stage, tenderness may often be elicited by palpation Leukopenia is a characteristic finding at this time, and toward the end of the preicteric phase many large atypical lymphocytes, similar to those found in patients with infectious mononucleosis, are often seen (Havens and Marck, 1946). Many patients have subjective improvement toward the end of the preicteric phase, lasting 1 or 2 days until jaundice appears

The icteric phase is ushered in with a return of gastro-intestinal symptoms It may last in adults from 1 to 10 weeks, averaging 6 weeks Some patients may have slight jaundice for several months Major symptoms and signs in the icteric phase are again anorexia, abdominal discomfort, usually related to pain in the right upper quadrant or epigastrium, nausea and often vomiting The liver becomes enlarged and more tender and usually is easily palpable. The spleen is palpable and tender in a fair percentage of patients These symptoms and signs may last only a short time or as long as a month, although usually improvement occurs within 2 weeks at the time when jaundice has reached its maximum intensity and has begun to wane. Considerable loss of weight is not uncommon, but ■ jaundice diminishes, a sense of well-being and appetite return Convalescence is generally uneventful and rapid. Fatalities are uncommon, and the mortality ranges from 1 to 3 per 1,000. As in a number of virus diseases, the older the patient the more severe the illness and the higher the mortality (Muller, 1947, *Sherman and Eichenwald, 1956*). *Death* may occur early in the disease, after 3 to 10 days of illness, or later, 3 to 8 weeks after onset *Sudden appearance of restlessness, mental con-*fusion, loss of emotional control, coma and hemorrhagic phenomena carries a grave prognosis True complications are rare, but occasionally patients develop pneumonia and, very rarely, agranulocytosis, lymphocytic meningitis or myelitis The frequency of relapse has been reported to range from 0 6 to as much as 18 per cent of the adult cases, although the high rates are most uncommon In a fair percentage of so-called "relapses," the only evidence is furnishd by laboratory tests that indicate a mild worsening of hepatic function. In another group of patients, a relapse manifests itself by a return of symptoms or physical signs of the icteric phase of disease, although it is usually less severe than the initial illness Complete recovery occurs in most patients both with or without relapses

A few patients have hepatic dysfunction prolonged beyond the usually expected time of recovery, with or without signs or symp-

bromsulphalein (Post et al, 1950) A large proportion of this group are asymptomatic, and it is questionable to what degree the slightly abnormal tests of hepatic function should be regarded as actual manifestations of illness In most of these cases, the degree of functional impairment of the liver and the clinical condition are apparently compatible with full activity and eventual complete recovery (Klatskin and Rappaport, 1947; Kunkel et al, 1947) Another smaller group of patients have more prolonged anorexia, lassitude and epigastric discomfort, with jaundice, enlargement of the liver, and spider angioma Eventual improvement is usually to

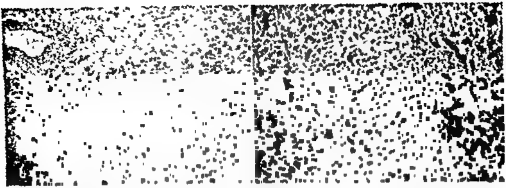

Fig 98 (*Left*) Photomicrograph (low power) of autopsy specimen, illustrating an acute destructive lesion of the liver from a case of infectious hepatitis in which death

of Dr G Klatskin)

be expected, although a small percentage of such patients have a progression of disease and develop severe postnecrotic scarring of the liver (Watson and Hoffbauer, 1946, Sherlock, 1948, Kunkel and Labby, 1950) In these, the ultimate prognosis is poor. Women in the age group beyond the menopause seem to be more prone to this form of chronic hepatitis than do men (Jersild, 1945).

Conditions that cause relapse or prolongation of disease are poorly defined It has been suggested that inadequate rest, poor diet, intercurrent infections, previous hepatic disease, and a long history of alcoholism or dietary insufficiencies may be predisposing factors, although little is known about these points

Pathologic Picture

Extrahepatic lesions found at necropsy include phlegmonous inflammation and hemorrhage of the stomach and the intestinal walls The spleen is frequently enlarged and congested with follicular hyperplasia Large edematous mesenteric and peripheral lymph nodes are found in patients dying in relatively early stages of the disease It seems that these rather scanty lesions fail to reflect the generalized character of this disease of which the hepatic lesion may be but one, albeit a spectacular, lesion Knowledge of pathologic changes in the liver has been acquired from biopsies of the liver taken at various stages throughout the course of the disease (Roholm and Iversen, 1939) and at necropsy (Fig 98). Early changes consist of swelling and irregularity of shape of hepatic

ration in most cases at the end of 2 or 3 months Slight residual periportal infiltration may persist in some patients for several months longer In the fulminant form of disease (Lucké and Mallory, 1946) in which death occurs within 10 days after onset, the

perplasia The lobular remnant contains numerous proliferated macrophages and erythrocytes, so that the liver may resemble a spongy framework infiltrated with inflammatory cells and blood. In such cases, death may occur very early, within 3 or 4 days of onset, before jaundice appears In the *subacute* form of disease in which death occurs 3 to 6 weeks after onset, the liver is frequently firm, reduced in size, and the cut surface may be granular. Destruction of parenchymal cells is neither complete nor uniform, and considerable evidence of regeneration is found

TABLE 24. COMPARISON OF CERTAIN FEATURES OF INFECTIOUS HEPATITIS AND SERUM HEPATITIS AND THEIR CAUSATIVE AGENTS, VIRUS A AND VIRUS B

CLINICAL AND EPIDEMIOLOGIC FEATURE	INFECTIOUS HEPATITIS	SERUM HEPATITIS
Incubation period	15 to 40 days	60 to 160 days
Type of onset	Acute	Insidious
Fever—over 38° C (100.4° F)	Common	Uncommon
Seasonal incidence	Autumn-winter	Year round
Age preference	Children and young adults	Any age
	Virus A	Virus B
Filtrability		
Seitz EK filter	Passed	Passed
Gradocol membrane with pore size 52 mμ	Not done	Passed
Susceptible host	Man	Man
Virus in feces	Incubation period and acute phase	Not demonstrated
Virus in duodenal contents	Acute phase	Not done
Virus in blood	3 days before onset and in acute phase	Incubation period and acute phase
Route of infection (experimental)	Oral and parenteral	Parenteral
Duration of carrier state,		
blood	As long as 8 months (one adult)	As long as 5 years (one adult)
feces	As long as 16 months (one child)	Not demonstrated
Immunity		
homologous	Present	Equivocal
heterologous	None apparent	None apparent
Prophylactic value of gamma globulin	Good	Equivocal

EXPERIMENTAL INFECTION; HOST RANGE

Various "Hepatitis Viruses"

In spite of numerous attempts to produce infectious (or serum) hepatitis in hosts other than man, these have been almost universally negative. A summary of these negative attempts as of 1949 was made by Colbert, and 2 years later in a British report (MacCallum et al., 1951), and again later in the United States in a report of a Symposium of the National Academy of Sciences—National Research Council (1954). These negative attempts have included the use of many different species of monkeys and chimpanzees. Occasional transmission of human hepatitis virus to pigs (Andersen and Tulinius, 1938), birds (Herzberg, 1943, Lucké and Radcliffe, 1949), embryonated eggs (Siede and Meding, 1941; Henle et al., 1950) and rats (MacCallum and Miles, 1946) has been claimed but not confirmed. More recently, ducks have been studied in this connection (Hanson and Alberts, 1956).

Various spontaneously appearing agents, some of which may or may not be related to human hepatitis virus, have been reported to be capable of producing hepatic lesions in sup-

TABLE 25. RESULTS OF EXPOSURE OF HEPATITIS VIRUSES A AND B TO VARIOUS PHYSICAL AND CHEMICAL AGENTS AS DETERMINED BY EXPERIMENTS IN VOLUNTEERS

	Virus A	Virus B
Temperature resistance		
Room temperature, 3 months	—	Survived
Room temperature, 8 months	—	Survived

* Inactivation followed adequate coagulation and settling of water

posedly healthy mice (Olitsky and Casals, 1945, Nelson, 1952, Hara et al, 1952, Lackey et al, 1953, Jordan and Mirick, 1955) In 1951, Gledhill and Andrewes described a rather special kind of hepatitis in mice which was subsequently shown by the same authors (cf Niven et al, 1952) to be a complex infection due to two agents acting together the mouse hepatitis virus and another parasite, *Eperythrozoon coccoides* It is also clear that there are several agents, including the viruses of lymphocytic choriomeningitis and ectromelia, that may cause murine hepatitis In dogs, agents that give rise to hepatitis include infectious canine hepatitis virus (Rubarth, 1945). Such viral agents seem to be characteristically limited in their host range Nothing is known about a relationship between these agents and those producing hepatitis in man

Henle et al (1950) reported the propagation of virus A in tissue culture and embryonated eggs After several transfers, the virus was reidentified by suggestive but not conclusive tests in volunteers (Drake et al, 1950) Others, who have claimed the growth of human hepatitis virus in the developing chick embryo, include Dresel et al (1943), Benda et al (1949), and Essen and Lembke (1949), but none of this work has been confirmed

ETIOLOGY

From experiments with volunteers, it has been shown that infectious hepatitis virus (virus A) has certain properties that are listed in Tables 24 and 25 The actual number of recognized properties is small because of the

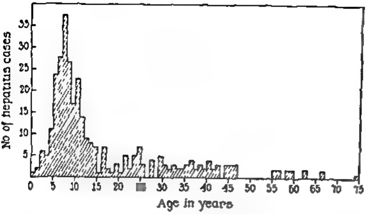

FIG. 99. The age incidence of *hepatitis epidemica* in Germany prior to World War II. Data are from two outbreaks occurring in Hamburg and Wilhelmsberg, respectively (von Bormann, F., 1940, Hepatitis epidemica, Ergebn. inn. Med u Kinderh *58, 201*)

obvious handicaps in working with this agent However, it passes through bacteria-tight filters and is transmissible in series to man; it is resistant to a temperature of 56° C for at least 30 minutes, and withstands chlorination for 30 minutes, viz, 1 part chlorine residual per million (Neefe et al, 1945a) as well as the action of certain chemicals that ordinarily destroy bacteria

Transmission

As far as is known, man continues to be the only original source of this agent, which is recoverable from the blood and the feces of patients in the incubation period as well as the preicteric or early icteric phase of disease and may be transmitted to volunteers by feeding or by parenteral inoculation of infectious material Several attempts to detect virus in the urine or the nasopharyngeal washings of patients at similar periods have yielded contradictory results (Findlay and Willcox, 1945) In general, they have been unsuccessful, and the balance of evidence is that intestinal excretion of this agent represents its main infective source

The period of infectivity of patients has been investigated (Havens, 1946a), but the number of experiments designed to determine when virus actually appears in the blood and the feces (presumably during the incubation period) and how long it remains there is unfortunately small However, it has been found in the blood 3 days before the onset of the disease (Francis et al, 1946) and also in the feces during the incubation period (Ward and Krugman, 1957). Attempts to recover virus A from the blood and the feces in adult patients 1 month after the onset of disease and also 3 weeks after disappearance of jaundice (Neefe et al, 1945c) have been unsuccessful However, Murray et al (1955a) found virus (presumably A) in the blood of 1 patient 8 months after recovery when tests of hepatic function were normal. This, in conjunction with the fact that a certain percentage of recipients of transfusions of whole blood acquire hepatitis after a short incubation period, suggests that the carrier state in the blood exists more frequently than previously suspected Infants can be fecal carriers of this virus for months (Capps et al, 1950). Further discussion of viremia and of hepatitis virus B is found in the section on *serum hepatitis*

Immune Reactions and Immunity

At present, the absence of specific diagnostic tests for the identification of the various types of human hepatitis viruses renders it most difficult to reach definitive conclusions about immunity. A number of serologic reactions have been described, but most of them have been accepted as nonspecific. A summary of these tests has been made by Havens (1954) Some of them are mentioned later.

Neefe et al. (1946) and Gauld (1946) suggest that one attack of infectious hepatitis is followed by homologous immunity The natural history of infectious hepatitis also supports the concept of a widespread adult immunity in some areas brought about by subclinical (and clinical) infection often acquired

in children and young adults than it is in

older groups (Fig 99). Among U S troops quartered in an endemic area of Europe in 1947-50, the morbidity rate in men of 20 years of age was about twice as great as that in men of 40 (Paul and Gardner, 1950).

The demonstration of the protective effect of normal human gamma globulin when administered during the incubation of infectious hepatitis suggests the presence of certain neutralizing substances in the blood of the normal human adult population, probably as a result of a previous clinical or subclinical attack of the disease Immunity has also been demonstrated experimentally (Neefe et al, 1945b, 1946; Havens, 1946b) in volunteers convalescent from hepatitis caused by 2 different strains of virus A when challenged with the homologous strain 6 to 9 months after their initial infection Partial cross-immunity was also shown to exist between these 2 strains of virus A A history of second attacks of hepatitis is said to be obtainable in from 2 to 5 per cent of patients Again, the lack of a specific diagnostic test makes it difficult to evaluate such evidence, for one cannot eliminate the possibility of prior infection due to virus B or to other as yet unidentified and immunologically distinct strains of hepatitis virus. The failure to obtain these viruses in a form in which their antigenic properties can be studied has been the main reason why information on this point is very incomplete

Diagnosis

In the absence of specific immunologic tests, diagnosis in the preicteric phase must be made on clinical and epidemiologic evidence Early in the disease, percussion tenderness over the liver and the detection of posterior cervical adenopathy and splenomegaly may be of assistance Abnormal retention of bromsulphalein is usually the first test of hepatic function to become positive, and this may occur as early as the second day of fever The cephalin-cholesterol flocculation and the thymol turbidity tests become positive somewhat later, and ordinarily bilirubin appears in the urine toward the end of the preicteric phase just before jaundice is apparent (Fig 97) The detection of bilirubinuria is a simple but reliable diagnostic aid at this time and may also be helpful in nonicteric hepatitis Its value has been emphasized by Swift et al (1950b). Leukopenia with relative lymphocytosis is characteristic in the preicteric phase and it simulates that seen in the early stages of infectious mononucleosis

The sera of a very few patients with infectious hepatitis contain a heterogenetic antibody that agglutinates sheep erythrocytes Some sera also contain antibodies that agglutinate rabbit erythrocytes and fix complement when combined with an antigen made from human liver. These tests have not turned out to be of diagnostic significance. Indeed, the absence of agglutinins for sheep cells has been a point of differentiation between the hepatitis of infectious mononucleosis and that of infectious or serum hepatitis

During the febrile preicteric phase, diseases that may be confused are infectious mono-

fluenza The subsequent course and the demonstration of specific etiologic agents or their antibodies in the case of these other diseases assist in making the diagnosis

When jaundice is present, the following conditions may be considered acute and subacute cholangitis, Weil's disease and yellow fever Jaundice may also develop occasionally in a variety of acute and chronic infections, as in infectious mononucleosis, malaria brucellosis, amebiasis, pneumococcic pneumonia, septicemias, syphilis, both congenital and acquired (secondary) In addition to jaundice associated with various infections, other types of jaundice to be distinguished include (1) hemolytic, either congenital or acquired, (2)

carcinoma of the liver, and (3) obstructive, due to obstruction of the biliary tract by calculus or neoplasm

A diagnosis of chronic viral hepatitis depends on the demonstration of hepatic dysfunction or histologic alterations in the liver, with or without clinical signs or symptoms Although the wide variability in the duration of illness does not justify this diagnosis until at least 6 months have elapsed from the onset of acute hepatitis, the reappearance and the persistence of anorexia, easy fatigability, and upper abdominal discomfort beyond this time

suggest chronic hepatitis. The presence of prolonged enlargement and tenderness of the liver, *jaundice and splenomegaly, and abnormal* tests of liver function lend supportive evidence, and in such patients abnormality of the bromsulphalein-retention test is the most reliable evidence of chronic hepatic dysfunction. Cholangiolar obstruction occurs at times, with severe jaundice and increased amounts of serum alkaline phosphatase and total cholesterol. Differential diagnosis from extrahepatic obstruction may be particularly difficult in such patients, and biopsy of the liver, or even exploratory laparotomy, may be indicated at times In a certain number of patients who have had acute hepatitis, it is most difficult to interpret their persistent subjective complaints in the absence of objective evidence of hepatic disease It is recognized that anorexia, fatigue and abdominal discomfort may occur long after the expected time of recovery when little or no evidence of hepatic dysfunction or histologic alterations in the liver is found; the term "posthepatitis syndrome" has been applied to this condition (Sherlock and Walshe, 1946).

Treatment

Acute Hepatitis. Treatment of the disease is symptomatic and, under the circumstances of normal civilian life, there is little need to hospitalize patients if they are not seriously ill The most important therapeutic principles are the provision of adequate rest in bed and a well-balanced, palatable, nutritious diet Procedures outlined by Chalmers et al (1955) are recommended They advocate an *optimal diet consisting of about 3,000 calories* and containing approximately 150 Gm each of protein and fat. Intakes above this level *should be ad lib. Although fried and greasy* foods may cause indigestion, the fat contained in meat, eggs and dairy products is not harmful and adds greatly to the palatability of the diet. During the stage of severe anorexia, the patient should be urged to take frequent small feedings. Intravenous glucose solutions should be administered when necessary to maintain a minimal caloric fluid intake. Although the forcing of a high-protein, high-fat diet, by stomach tube if necessary, in patients with disease of average severity has been demonstrated to hasten recovery, critically ill patients with fulminating disease or impending hepatic coma may be harmed by ex*cess dietary protein. Therefore,* in these few very ill patients it is probably unwise to administer more than a maintenance quantity of protein, and under certain circumstances protein should be completely omitted from the diet during the critical phase of illness Intra*venous protein hydrolysates, plasma* or blood transfusions have no place in the nutritional therapy of patients with uncomplicated infectious hepatitis The duration of rest in bed, which is recommended in this disease, has been a controversial matter. Military experience early in World War II indicated that too brief a period of bed rest in depleted patients with this disease was followed not infrequently by relapse. Subsequent experience with troops who were in good physical condition before contracting the disease (Gardner et al., 1949; Swift et al , 1950a) suggested [illegible]

Chalmers et al. (1955) have pointed out that physical activity to the point of fatigue may be harmful. Patients should be urged to rest *in bed as long as acute symptoms* persist Once they begin to feel well, regardless of the degree of jaundice, they should not be forced to stay in bed more than 1 hour after each meal. However, restriction to the room or the hospital ward is essential to decrease undue activity or exertion. Allowing this type of *ad lib* activity (without any required exertion) circumvents the usual delay necessary for recuperation from the effects of prolonged *rest in bed and appreciably* shortens the period of convalescence.

Patients so treated may begin physical re*conditioning after the total serum* bilirubin is below 1.5 mg. per 100 ml. and the bromsulphalein retention in 45 minutes is below 6 per cent for a period of not less than 1 week Patients whose bromsulphalein retention stabilizes between 5 and 10 per cent may begin physical reconditioning with safety. Those with persistently higher levels will require individual management. During the period of reconditioning, it is well to follow all patients with weekly physical examinations, serum bilirubin tests and bromsulphalein tests until convalescence is complete—usually a matter

of 2 to 4 weeks Recurrent abnormalities will occur rarely and are probably indication for diminishing activity In the average adult military case with jaundice, the period of hospitalization is 60 days.

The administration of corticosteroids or ACTH in the acute phase of viral hepatitis is usually followed by a speedy return of a sense of well-being and appetite, a sharp diminution in serum bilirubin within 1 week after institution of therapy, and a shortening of the total period of jaundice in amount of 1 week (Colbert et al, 1951, Ducci and Katz, 1955) However, untoward effects, including "mooning" of the face, ascites, edema and hypertension, are frequently observed, and relapse following cessation of too short a course of therapy is not uncommon (Evans et al, 1953) For these reasons, the routine use of ACTH or corticosteroids is not recommended in patients with hepatitis of average severity Nevertheless, there are situations in which special consideration for therapy with corticosteroids or ACTH must be given (Nelson, 1957) These include (1) patients with severe progressive disease, intractable vomiting, and with serum bilirubin in excess of 15 mg per 100 ml., (2) patients with disease of such severity that hepatic coma is imminent or present, and (3) patients with cholangiolitic hepatitis

When coma occurs in the course of acute hepatitis, recovery is rare In such situations, Ducci and Katz (1952) first showed that cortisone used in conjunction with other measures ordinarily employed for treating such patients may have beneficial effects These workers and others, using a regimen of 500 mg cortisone injected intramuscularly every 8 hours for 1 to 2 days, followed by rapidly diminishing doses over the next 14 to 21 days, have reported survival of a small number of patients In such patients it is also recommended (1) that chloramphenicol be given (Farquhar et al, 1950; Shaffer et al, 1950) in amounts of 250 mg every 6 hours by mouth, supplemented by 100 mg every 6 hours intravenously, and (2) that from 2,000 to 3,000 ml of a solution of 10 per cent dextrose in sterile distilled water be given intravenously in constant drip daily during the acute phase of hepatic decompensation.

Chronic Hepatitis. *In certain patients with mild though continued functional hepatic disability as the only manifestation of sequelae of acute hepatitis, it would seem unnecessary to curtail their activity for any therapeutic reasons. However, another group of patients with symptoms and signs of disease, including prolonged anorexia, epigastric discomfort (with or without jaundice), and an enlarged, tender liver, may require rest in bed for prolonged periods, with special attention to a well-balanced, nutritious diet. In those patients whose disease progresses to severe postnecrotic scarring of the liver, the usual therapeutic regimen employed for persons with Laennec's cirrhosis is recommended but is frequently disappointing The intravenous administration of salt-poor albumin appears to be of some value in certain individual cases of this type*

Epidemiology

Prevalence and Geographic Distribution. In spite of inadequate information, so-called viral hepatitis probably occurs in nearly all inhabited areas of the globe. However, there are certain regions with an established record of high endemic prevalence for infectious hepatitis,* of which the Middle East and the Mediterranean littoral are examples Military outbreaks are proverbial there, and over the past 150 years these have occurred repeatedly among troops from Europe, Australia and North America which have been brought into such endemic areas

porting of cases during the past decade has been irregular and often on a voluntary basis It would be difficult to say what the relative incidence rates in this country by states might be. That it is a relatively common disease throughout the nation few would deny In Scandinavian countries, long-term information on the incidence of hepatitis has been more nearly complete than elsewhere This disease has been notifiable in Denmark since 1928 (Fig. 100) Here, as in some other countries in temperate climates in which sanitary facilities are good, the incidence has varied, with waves of increased frequency

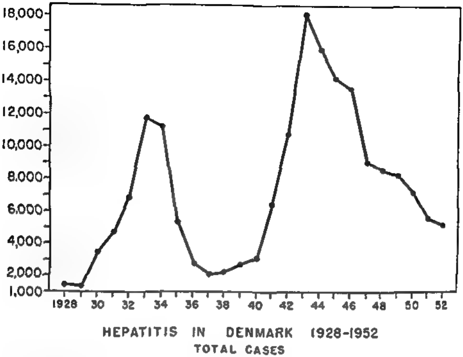

FIG 100. (From Marie Lindhardt, Director, Statistical Section, National Health Service of Denmark, Copenhagen, Denmark)

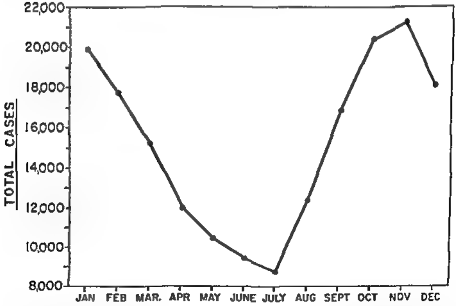

FIG 101. Seasonal trend of hepatitis in Denmark, 1928-1952. (From Marie Lindhardt, Director, Statistical Section, National Health Service of Denmark, Copenhagen, Denmark)

covering several years, notably during the occupation by German troops. How representative of northern Europe this picture may be is not known. Certainly, it is unlikely that the trends in Scandinavia would be similar to those of a tropical country or to those of a country with substandard conditions of sanitation.

In many areas there is a distinct seasonal trend, with a sudden increase in prevalence in the late summer and autumn, often building up to epidemic proportions during early winter and soon declining. However, the epidemic season may reach a peak in late winter and extend well into the spring (Fig. 101).

Transmission. Most present evidence indicates that infectious hepatitis is usually spread through some form of person-to-person association, although water-borne, food-borne and milk-borne epidemics have been described. Nevertheless, man represents the main source and reservoir of the infection, for as yet no extrahuman host in the form of an animal, a bird or an arthropod has been discovered in which hepatitis viruses are known to multiply or survive, although the possibility of mechanical transmission by a biting insect never has been eliminated nor has it been investigated adequately.

There is good evidence to indicate that the intestinal-oral circuit is the principal route in this natural person-to-person spread. This is based upon experimental tests with volunteers that indicate the frequency with which hepatitis virus A can be demonstrated in human feces during acute stages of the disease, and the ease with which this disease may be produced by feeding such material to man. Although some epidemiologic observations point to a respiratory mode of spread, none of the experimental tests on this has been sufficiently satisfactory (due to technical or other reasons) for definite conclusions to be drawn from the results. In any event, a respiratory type of spread seems unlikely. As in poliomyelitis, personal and close contact with infective people, particularly children, probably provides the source of exposure for a great majority of orally acquired cases of infectious hepatitis.

Evidence to substantiate the fact that the intestinal-oral circuit is involved is based upon the water-borne epidemics of infectious hepatitis and the [illegible]

of a variety of enteric infections. Not infrequently outbreaks of hepatitis are preceded by a wave of "gastroenteric illness," presumably of bacterial origin. An example of this has been reported by Tucker et al. (1954) in the form of water-borne gastroenteritis and hepatitis epidemics that sequentially occurred at a church camp in Tennessee in 1952. It was suggested here, as elsewhere, that both infections, acute gastroenteritis and infectious hepatitis, were related to the same source, and the difference in the lengths of the respective incubation periods (i.e., a few days in the former and about 3 weeks in the latter) gave rise to 2 sequential waves of illness. Military observations also record that the incidence of hepatitis has been highest when and where the sanitation of camps has been poor. Civilian evidence further testifies to the frequency with which visitors acquire hepatitis in tropical or semitropical areas, and also where poor sanitary facilities exist. Again, in institutions for mentally deficient individuals, hepatitis rates have been higher in those buildings housing individuals with the lowest mental capacity and where, as a consequence, the poorest sanitation can be maintained.

Nevertheless, as viral hepatitis is easily spread by intimate association among people, epidemics of this disease commonly result from some form of person-to-person dissemination, within institutions, dwelling houses or apartment houses where sanitary facilities are far from substandard. Such outbreaks often occur in the best-regulated families. Within some "communities," it may well be that a large unsuspected source of virus maintains itself in the form of inapparent, infantile or juvenile cases, and under circumstances of unsuspected exposure it is small wonder that the disease spreads readily to the susceptibles in the population.

The artificial parenteral dissemination of virus A, in a manner comparable with that usually seen with serum hepatitis (virus B), through the use of contaminated blood or serum, and by improperly sterilized syringes or needles as described by Droller (1945), is a point for consideration. The stability of the icterogenic agent and the infectivity of small quantities of blood suggest that infectious hepatitis probably has been transmitted unintentionally more often than is realized.

Types of Epidemics (1) *Water-borne.* There are now many examples of the explosive water-borne epidemic. Prominent among them have been those reported in summer

camps (Neefe and Stokes, 1945, Tucker et al, 1954) A notable recent example of a huge water-borne urban epidemic of infectious hepatitis is one that occurred in 1956 in the city of Delhi, India (Melnick, 1957) It is said to have accounted for some 30,000 cases (2) *Food-borne and Food Handlers* Food-borne (including milk-borne) epidemics have been described in military and civilian experience (Read et al, 1946; Murphy et al, 1946), and of particular interest was an epidemic apparently resulting from eating contaminated oysters (Gard and Alin, 1957) It is more than likely that food handlers in various infectious stages of inapparent or clinical hepatitis play an important role in the spread of virus A

Institutional Outbreaks. These are common in orphan asylums, boarding schools, and notoriously so in mental institutions In some large mental institutions (i e., with a population of 2,000 or more), hepatitis and salmonellosis may become endemic, and over the course of several years cases may continue to appear in large or small numbers each month both in inmates and in attendants (Ward et al, 1957) This situation has been ascribed to the bowel habits of mentally deficient inmates, be they children or adults, and to the great difficulties of maintaining adequate standards of environmental sanitation even in the best-run institutions

Family Epidemics. These are so common and well known as hardly to deserve mention In a family consisting of 4 or 5 members, a usual story is that 1 child contracts a mild case of "jaundice" first, and not much is made of it. About a month later, another child becomes jaundiced or perhaps a parent Usually much more attention is paid to the case occurring in an adult, although to the epidemiologist the others would seem to be of equal importance The rather long interval between cases offers an opportunity to use gamma globulin as a prophylactic measure in such situations

Age Distribution. Under most circumstances, infectious hepatitis is essentially a disease of childhood Indeed, as a general statement, children are said to account for 65 per cent of the cases, with the bulk of them occurring between the ages of 5 and 15 (cf. Fig 99). It is obvious, as has already been mentioned, that this distribution may vary considerably under different environmental conditions, in different places or at different times in the same place This concentration of the disease in juveniles has been responsible for many misconceptions regarding the local incidence of viral hepatitis In endemic areas, infection and immunity are acquired so early in life and at an age when the clinical symptoms are about at the vanishing point that they may be completely overlooked Mild diarrhea may be the only symptom Superficially, therefore, the disease often seems to be conspicuous by its absence Only does its presence come to light when susceptible visitors enter the endemic area

This mildness of infantile and childhood hepatitis has not received the emphasis it deserves, particularly as there is no evidence that such mild cases are any the less infectious, indeed, as the duration of the intestinal carrier state in infants is so prolonged, they may be more infectious In this sense, these long-term infant carriers (Capps et al, 1950) can actually serve as a reservoir of infection

Control Measures

The reporting of all cases (including suspected cases) is a useful measure, and in some places it is required For the protection of intimately exposed persons, the prompt administration of normal immune globulin has proved to be a valuable procedure, particularly in the case of the adult members of a household exposed to infectious hepatitis Illness may be aborted if immune globulin is given during the incubation period or perhaps just before exposure It may be effective when given as late as 6 days before the onset of disease (Stokes and Neefe, 1945, Havens and Paul, 1945, Gellis et al, 1945) Doses of 0 06 to 0 12 cc. per pound of body weight are protective when given intramuscularly, although it has been shown that as little as 0 01 cc per pound of body weight is effective It has been estimated that passive protection lasts from 6 to 8 weeks However, observations of groups of children inoculated with gamma globulin and subsequently exposed to hepatitis virus under endemic conditions over a period of several months suggest that more permanent protection may occur. The reason for this is not yet understood (Stokes et al, 1951).

As for general methods to curtail the spread of virus A, procedures that tend to interrupt the intestinal-oral route should be carried out During any institutional or camp outbreak, attention should be directed toward the gen-

eral sanitation of the site and of the water supply, fly abatement, sterilization of food receptacles, and prevention of fecal contamination of food and milk supplies The degree of chlorination effective against hepatitis virus has not yet been determined Detection of healthy human carriers or subclinical cases is impossible at present because of the lack of suitable laboratory technics Since it is as yet unknown how long virus remains in stools or blood, it is advisable to regard the stools as potentially infectious for at least 1 month after the onset of disease and to recommend that patients do not act as donors of blood except under the special conditions described in the section on serum hepatitis Every possible effort should be made to avoid employing food handlers who may be fecal carriers of the virus and to keep food handlers free from infection Particular effort should be made to clean properly and to sterilize with heat all needles and syringes that come in contact with the blood of such patients There will be further discussion of this important point in the section on serum hepatitis

SERUM HEPATITIS

Introduction

Serum hepatitis is described as a form of disease ordinarily produced by the parenteral inoculation of human blood or its products obtained from a person who, though as a rule not apparently ill, is carrying virus B in his blood The fact that virus A is also carried in the blood and may be transmitted parenterally limits the usefulness of this definition, and at present it is generally assumed that if hepatitis acquired in this way has a short incubation period (15 to 40 days), it is the result of the artificial transmission of virus A, whereas a long incubation period (60 to 160 days) implicates virus B as the cause of disease The recent description by Ward et al (1957) of epidemic hepatitis (presumably due to virus A) with an intermediate incubation period of 35 to 50 days and the fact that a fair percentage of patients acquiring hepatitis from transfusions of whole blood have incubation periods of a similar length emphasize the inadequacy of nomenclature based on length of incubation period

History

Under the terms of this arbitrary definition, it is likely that this type of hepatitis has existed for some time, its incidence augmented during recent years by the increasing use of human blood and certain of its products and by the frequency of various parenteral penetrations The epidemics of jaundice following vaccination for smallpox in Germany, Lurman, 1885, in the 1880's were doubtless examples of this disease. Likewise, the early suggestions of Stokes et al, 1920, and Ruge, 1927, that the jaundice occurring in luetic patients receiving heavy-metal therapy was due to an infectious agent were probably correct. However, credit for the first recognition of the true nature of the condition goes to a group of Swedish physicians (Flaum et al, 1926) who described an

atitis may be divided into two groups (1) those who are infected by improperly sterilized syringes, needles or instruments employed in giving medications, withdrawing blood for laboratory tests, or performing various procedures in dental work or even tattooing, and (2) those who are infected by the administration of transfusions of blood or plasma, or contaminated products of human blood such as convalescent serum, dried serum, fibrinogen, thrombin, Cohn's Fraction IV, or vaccines containing human serum or plasma In the years just prior to and early in World War II, thousands of cases of serum hepatitis occurred, particularly in military personnel but also in civilians, after the injection of yellow fever vaccine that contained human serum (Fox et al, 1942, Sawyer et al, 1944) Subsequently, the widespread use of plasma and blood particularly in depleted patients both military and civilian, together with the failure to develop satisfactory methods of sterilizing these materials to render them free from hepatitis virus, and the frequency and the prolonged duration of the carrier state augmented the seriousness of this hazard to the point where it has emerged as one of the important medical problems of the times The potential magnitude of risk is attested by the fact that 21 9 per cent of certain groups of soldiers receiving transfusions of blood and plasma and 3 6 per cent of other groups receiving

whole blood alone in the Korean War contracted serum hepatitis (Sborov et al, 1953) Among civilians, the incidence has not reached these proportions, although rates as high as 11 9 per cent have been reported following the use of plasma from large pools (Murphy and Workman, 1953) In addition, the protracted disruption of civilian economy during the postwar years, with short supplies in many parts of the world, created situations favorable to inadequate sterilization of instruments and to the artificial transmission of hepatitis virus in clinics and physicians' offices (Wewalka, 1953)

Clinical Picture

With certain exceptions, serum hepatitis is clinically and pathologically similar to infectious hepatitis However, its incubation period is much longer, and its onset is more apt to be insidious and accompanied by less fever (Turner et al, 1944) Worthy of mention also is the frequency with which urticaria and arthralgia precede the appearance of jaundice The clinical course is usually similar in severity to that of infectious hepatitis when otherwise healthy patients in the same age groups are compared, however, serum hepatitis, by the nature of its way of transmission, so frequently occurs in sick, debilitated and often elderly patients that in them as well as in young children (McNalty, 1938) its course may be much more severe and the mortality greater The same therapeutic principles apply to both conditions

Etiology

The little that is known about the properties of virus B has also been derived from experiments in volunteers Its exact size is not defined, but it passes through a gradocol membrane of 52 mμ average pore diameter, indicating a size of 26 mμ or less (McCollum, 1952) It is also highly resistant to inactivation by various physical and chemical agents; is transmissible to man in series; and, under certain circumstances, evokes homologous immunity, although little is known about this response and its status is equivocal (Table 24)

Transmission

Man is apparently the only original source of this agent, which is recoverable from the blood of carriers and from patients during the long incubation period or early icteric phase of disease and may be transmitted to volunteers by parenteral inoculation of infectious material Limited attempts to detect virus in the feces, the urine and the nasopharyngeal washings (with one exception—Findlay and Martin, 1943) have been unsuccessful, and the available evidence suggests that the blood of human carriers represents its main infective source.

The duration of infectivity following recognized hepatitis is unknown A small number of earlier studies with experimentally infected volunteers suggested that virus A and virus B were not present in the blood when tested at varying times ranging from 1 to 12 months after the onset of disease However, subsequent studies revealed the presence of virus B in the blood of one patient 4 months after recovery and of virus A in the blood of another patient 8 months after recovery. Tests of hepatic function were normal at the times when viremia was present (Murray et al, 1955a) Of greater importance, however, is the accumulated evidence indicating that the carrier state without recognized disease is well equilibrated under certain circumstances and exists more frequently than previously suspected The prolonged period of viremia during the incubation periods of experimentally infected volunteers who were asymptomatic and without laboratory evidence of hepatic dysfunction is in support of this concept, as is the fact that, up to the present, those persons proved to be carriers have not, with a few exceptions, had a history of preceding hepatitis or jaundice. Clinical observations (Stokes et al, 1954) furnish supportive evidence in that virus B was found on two occasions, 2 years apart, in the blood of a patient who was asymptomatic and had normal hepatic function as determined by tests. During this period, the patient was delivered of a baby that died of hepatitis Another patient with so-called Laennec's cirrhosis has been proved to be a carrier of virus B for a period of 5½ years Lastly, the development of hepatitis by donors as long as several months to 1 year after their blood had been suspected or proved to have caused the disease in more than one recipient attests the equilibration that exists in

the carrier state (Murray et al, 1955a, Havens, 1956b)

Immune Reactions and Immunity

The nature and the degree of the immune response in serum hepatitis are poorly defined, since there is no method of measuring it at present. The fact that a large percentage of persons inoculated with virus B, either as volunteers or as patients receiving contaminated transfusions of blood or plasma, fail to contract hepatitis suggests either inherent or acquired resistance in the recipients, and the latter possibility is supported by the demonstration of homologous immunity in some of the studies in volunteers (Neefe et al, 1946; Murray, 1954) However, in contrast are (1) the failure to prevent infection with virus B in volunteers simultaneously inoculated with virus and with homologous convalescent gamma globulin (Drake et al, 1953); and (2) the irregular results of attempts to prevent serum hepatitis in field trials with different lots of normal human gamma globulin (Grossman et al, 1945, Duncan et al, 1947, Mirick, 1957) Of interest in this regard is the fact that infections with virus B, in contrast with those with virus A, apparently do not have a predilection for any period of life; all age groups appear to be susceptible It is not known whether the variability in protection against virus B is due to (1) insufficient exposure to virus because of the artificial way of transmission, (2) the failure to develop or maintain adequate immunity following exposure, or (3) the existence of multiple strains of virus that are immunologically unrelated or have a limited geographic distribution These questions are particularly pertinent when, as occasionally happens, multiple attacks of hepatitis occur in the same patient (Fig 102, Havens, 1956a)

Epidemiology

The geographic distribution of serum hepa-

d together in time and

tis, strains of virus (presumably B) have been found that produced hepatitis in volunteers with a long incubation period following par-

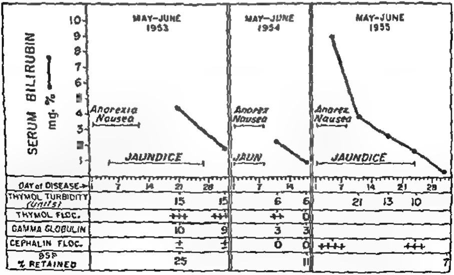

Fig 102. Course of disease during 3 separate attacks of viral hepatitis that occurred at intervals of 1 year in a narcotic addict (Havens, W. P, Jr., 1956, Viral hepatitis. multiple attacks in a narcotic addict, Ann Int. Med 44, 199-203)

whole blood alone in the Korean War contracted serum hepatitis (Sborov et al., 1953) Among civilians, the incidence has not reached these proportions, although rates as high as 11 9 per cent have been reported following the use of plasma from large pools (Murphy and Workman, 1953). In addition, the protracted disruption of civilian economy during the postwar years, with short supplies in many parts of the world, created situations favorable to inadequate sterilization of instruments and to the artificial transmission of hepatitis virus in clinics and physicians' offices (Wewalka, 1953)

Clinical Picture

With certain exceptions, serum hepatitis is clinically and pathologically similar to infectious hepatitis However, its incubation period is much longer, and its onset is more apt to be insidious and accompanied by less fever (Turner et al , 1944). Worthy of mention also is the frequency with which urticaria and arthralgia precede the appearance of jaundice The clinical course is usually similar in severity to that of infectious hepatitis when otherwise healthy patients in the same age groups are compared, however, serum hepatitis, by the nature of its way of transmission, so frequently occurs in sick, debilitated and often elderly patients that in them as well as in young children (McNalty, 1938) its course may be much more severe and the mortality greater The same therapeutic principles apply to both conditions

Etiology

The little that is known about the properties of virus B has also been derived from experiments in volunteers Its exact size is not defined, but it passes through a gradocol membrane of 52 mμ average pore diameter, indicating a size of 26 mμ or less (McCollum, 1952). It is also highly resistant to inactivation by various physical and chemical agents, is transmissible to man in series, and, under certain circumstances, evokes homologous immunity, although little is known about this response and its status is equivocal (Table 24).

Transmission

Man is apparently the only original source of this agent, which is recoverable from the blood of carriers and from patients during the long incubation period or early icteric phase of disease and may be transmitted to volunteers by parenteral inoculation of infectious material. Limited attempts to detect virus in the feces, the urine and the nasopharyngeal washings (with one exception—Findlay and Martin, 1943) have been unsuccessful, and the available evidence suggests that the blood of human carriers represents its main infective source

The duration of infectivity following recognized hepatitis is unknown. A small number of earlier studies with experimentally infected volunteers suggested that virus A and virus B were not present in the blood when tested at varying times ranging from 1 to 12 months after the onset of disease. However, subsequent studies revealed the presence of virus B in the blood of one patient 4 months after recovery and of virus A in the blood of another patient 8 months after recovery Tests of hepatic function were normal at the times when viremia was present (Murray et al , 1955a). Of greater importance, however, is the accumulated evidence indicating that the carrier state without recognized disease is well equilibrated under certain circumstances and exists more frequently than previously suspected The prolonged period of viremia during the incubation periods of experimentally infected volunteers who were asymptomatic and without laboratory evidence of hepatic dysfunction is in support of this concept, as is the fact that, up to the present, those persons proved to be carriers have not, with a few exceptions, had a history of preceding hepatitis or jaundice Clinical observations (Stokes et al , 1954) furnish supportive evidence in that virus B was found on two occasions, 2 years apart, in the blood of a patient who was asymptomatic and had normal hepatic function as determined by tests. During this period, the patient was delivered of a baby that died of hepatitis. Another patient with so-called Laennec's cirrhosis has been proved to be a carrier of virus B for a period of 5½ years Lastly, the development of hepatitis by donors as long as several months to 1 year after their blood had been suspected or proved to have caused the disease in more than one recipient attests the equilibration that exists in

is warranted even though it is only partially effective and at considerable sacrifice of blood.

Both virus A and virus B are unusually resistant to inactivation by physical and chemical agents, and there is no practicable way to treat all products of human blood to render them safe (Table 25) In this regard, it should be emphasized that there is no knowledge as to whether such commonly employed disinfectants as alcohol, ether and Zephiran are effective in destroying either virus A or virus B Accordingly, the probable inadequacy of disinfectants or detergents for so-called "cold sterilization" of surgical and dental instruments should be considered in this light. More is known of the resistance of virus B because of the numerous attempts that have been made to sterilize whole blood or plasma of this virus, utilizing ultraviolet light, heat, nitrogen mustard, sulfur-mustard, beta-propiolactone, and storage at room temperature for varying periods None of these methods has been proved to be effective consistently, although the evidence obtained experimentally and by follow-up studies of patients receiving plasma suggests that the use of one or more of them probably inactivates virus in some degree

Follow-up reports on patients receiving plasma believed to have been rendered safe by ultraviolet irradiation revealed an incidence of hepatitis as high as 11 9 per cent in one group of recipients (Murphy and Workman, 1953) Other studies by Murray et al (1955b) with a variety of technics revealed that irradiation as performed at present is not effective on a production basis or at levels of intensity that do not alter plasma proteins It is noteworthy, however, that under the conditions of these studies there apparently was some vitiating effect on virus B, since the volunteers inoculated with it had a lengthening of the incubation period and a milder disease

The greatly diminished incidence, or even absence, of hepatitis as determined by follow-up studies of recipients of plasma stored at room temperature for 6 months prompted Allen et al (1954) to propose this as a method of diminishing the hazard Experimentally, Murray et al (1954b) showed that known icterogenic plasma (containing virus B) stored at 70° F for 3 and 6 months was still infectious for volunteers, although the results indicated that the infectivity had been sharply reduced by storage for 6 months However, there are inherent limitations to this procedure, including the possibility of bacterial contamination and alterations of plasma proteins In addition, the necessity of waiting 6 months for inactivation limits the practicality of this method if rapid stockpiling of plasma were required

Although there is no single method of inactivating hepatitis virus that is applicable to human blood and all its components, ways of treating individual fractions have been devised that appear to be effective. The present method of preparing normal serum albumin includes heating to 60° C. for 10 hours, and this treatment has been shown to inactivate virus B when it is added to such preparations (Gellis et al, 1948) In addition, immune serum globulin and serum albumin prepared from known icterogenic plasma (containing virus B) by cold-ethanol fractionation, with subsequent heating of the albumin to 60° C for 10 hours, were not infectious in volunteers (Murray et al, 1955a) These results confirm the widely held clinical beliefs that neither immune serum globulin (Janeway, 1945, Hammon et al, 1952) nor normal serum albumin (Paine and Janeway, 1952) can be incriminated as causing serum hepatitis. However, of interest in this regard are recent observations indicating that virus B may not be completely removed when immune globulin is prepared (1) by ether fractionation (Cockburn et al, 1951) or (2) by zinc precipitation, nor does the latter step completely remove virus B from stable purified protein solution (S P P S unheated) (Murray et al, 1955a) Of importance also are the facts that (1) virus B withstands heating to 60° C for 4 hours in plasma (Murray and Diefenbach, 1953), and (2) attempts to inactivate it in whole blood by the addition of nitrogen mustard were unsuccessful (Drake et al, 1952) Preliminary experiments with sulfur-mustard and beta-propiolactone indicate that both of these materials can inactivate virus B, although the exact conditions for use and ultimate possibilities are not yet defined (Murray et al, 1955a).

Because of the carrier rate, the high degree of resistance of virus A and virus B to

enteral inoculation (Oliphant et al, 1943; Paul et al, 1945; Evans, 1950)

Comparison of Serum Hepatitis and Infectious Hepatitis

Certain differences are apparent between these 2 forms of hepatitis and their causative viruses (Table 24). Virus B is present in the circulating blood during the long incubation period as well as in the active stage of disease (Havens, 1946c), indeed, it has been demonstrated (Neefe et al, 1944) in the blood 87 days prior to the onset of symptoms It apparently produces disease only when inoculated parenterally (one exception *reported by MacCallum and Bauer, 1944), and symptoms appear insidiously after a long and variable incubation period of from 60 to* 160 days The disease is not so contagious as *infectious hepatitis, infection by close* contact has been suspected but is rare, and virus B has not been demonstrated in the feces as virus A has been in patients with infectious hepatitis These facts, together with the failure to produce hepatitis in volunteers by the oral administration of serum known to contain virus B, suggest that the mechanism whereby serum hepatitis is acquired in nature is obscure Immunologically, virus A and virus B appear to be distinct Studies on immunity in volunteers corroborate the epidemiologic experience that patients who have had infectious hepatitis are susceptible to serum hepatitis, and vice versa (Havens, *1945b, Neefe et al., 1945c) However, it is* not yet known whether this distinction represents actually *different viruses or antigeni*cally dissimilar strains of a single virus The curious apparent dependence of virus B on artificial transmission, its long incubation period, and the contradictory evidence of immunity following infection with it raise the question that the family that goes to make up virus B may represent variants of virus A, which is normally transmitted through the intestinal-oral route, produces disease after a short incubation period, and evokes a fairly solid immunity *in man The geographic co*existence of virus A and virus B, their im*munologic* distinctions, and the fact that both may be transmitted parenterally have sug*gested* that under certain circumstances both agents might be transmitted within a short interval or *even simultaneously, thereby* explaining the wide variations in length of incubation periods *sometimes seen during* localized outbreaks or even the occurrence of two attacks of disease (with a short and a long incubation period) in the same person (MacCallum, 1953, Wewalka, 1953).

Prevention and Control

Attention has been called to the fact that the emergence of serum hepatitis as a tremendous problem during the past 20 years occurred as a result of (1) the increasingly widespread use of human blood and its products; (2) the failure to develop reliable methods of sterilizing most of these materials of hepatitis virus, (3) the inadequate cleansing and sterilization of various instruments; (4) the frequency and the prolonged duration of *the carrier state. It has been estimated that* as many as 0.5 per cent of persons may be *carriers of virus under certain circumstances* The well-established role of the carrier state in *maintaining this infection, together with* the evidence suggesting that virus B may be transmitted from mother to child in utero, may account in part for its survival in nature at present (Stokes et al, 1954; Neefe et al, 1954, Murray et al, 1954a)

It is difficult to devise measures for the control of this disease because of the lack of specific serologic tests, susceptible laboratory animals and accurate methods for the detection of carriers The use of various tests of hepatic function (*particularly the thymol* turbidity) to detect carriers of virus may reveal *evidence of hepatic disease* and, in retrospect, has furnished evidence that certain donors whose blood produced hepatitis actually had hepatic disease Unfortunately, as many as 15 per cent of some groups of presumably normal persons have abnormal thymol turbidity tests The disproportion between this and the estimated carrier rate (up to 0 5%) is viewed with concern by those responsible *for blood banks* and makes *them* reluctant to reject so many donors on this *basis (Murray, 1955). In addition, the* fact that asymptomatic donors, with normal hepatic function as determined by tests, have been proved to be carriers of virus makes this an unreliable method of detection However, further consideration of this safeguard

physical and chemical agents, and the extreme infectivity (0 01 cc. of serum is infectious), the following precautions are recommended. Every parenteral penetration should be performed with instruments that have been thoroughly washed and then sterilized by boiling in water for 30 minutes, or by autoclaving at 121° C (15 lbs. pressure) for 20 minutes, or with dry heat (180° C for 1 hour) Donors with a history of hepatitis, donors with close contact with patients with hepatitis during the preceding 6 months, or donors who have received a transfusion of blood or plasma during the past 6 months should not be accepted except under conditions of emergency for single transfusions or under conditions in which their blood may be used in the preparation of a product such as albumin, which can be sterilized of hepatitis virus The need for transfusion of whole blood or plasma should be carefully evaluated in each patient and, in particular, the use of plasma should be sharply limited If necessary, plasma should be made from blood obtained from not more than 2 donors (World Health Report, 1953, Report New York Academy of Medicine, 1957)

Specifically, attempts to prevent serum hepatitis by the administration of normal human immune globulin have had equivocal results and, in general, have been regarded as unsuccessful However, the results of administration of 2 doses of 10 ml each 1 month apart, with the first dose given shortly after the transfusion, suggest that some protection may be possible (Grossman et al, 1945, Mirick, 1957). In addition, since a goodly percentage of hepatitis following transfusion of whole blood has a short incubation period, presumably due to virus A, one would be justified in giving normal immune globulin (0 06 cc /lb) intramuscularly within 1 week after transfusion, repeating this dosage in 1 month, if sufficient supply of this material were available.

man to man (Andrewes et al, 1951, Lovelock et al, 1952)

CLINICAL PICTURE

The incubation period appears to be relatively short. In transmission experiments in man, it was generally 2 or 3 days in duration with a range of 1 to 6 days (Andrewes, 1949) The onset is often fairly abrupt, and a feeling of roughness, soreness or dryness of the pharynx may be the first symptom Commonly, there is a sensation of irritation, fullness or congestion in the upper respiratory tract, particularly in the nasal passages or the nasopharynx Attacks of sneezing occur early and frequently A thin and watery nasal discharge, which may be copious, is almost invariably present in the early stages The discharge may become viscous or mucoid but rarely does it become mucopurulent before the second or third day An irritating nonproductive cough is present in about 30 per cent of patients Headache, malaise, chilly sensations, some aching of the extremities and lassitude are common complaints At times there is a slight increase in temperature, but this seldom exceeds 100° to 101° F

The nasal and the nasopharyngeal mucosa may be swollen, boggy and injected, one or both nostrils may become partially or completely occluded Postnasal discharge is uncommon during the first few days but may develop later The conjunctival vessels may be prominent, and the eyes may appear suffused The mucous membrane of the fauces and the posterior pharynx may be mildly injected The voice may become husky The upper anterior cervical lymph nodes may become slightly enlarged or tender The olfactory sense is usually diminished and may be lost temporarily The sense of taste may be reduced, and hearing may be moderately impaired Excoriations often develop at the nasal orifices, especially if the nasal discharge is copious In some persons herpetic lesions commonly appear on one or both lips (cf. Chap 38) The course is variable both as to duration and severity In children, particularly in the very young, colds tend to be more severe Fever is often a more prominent symptom, malaise and lassitude are more marked. The appetite may be markedly diminished

If complications do not develop, symptoms seldom persist longer than a week or two and in some colds may disappear after a few days Secondary bacterial infection of some area of the respiratory tract develops frequently, particularly in young children; the paranasal sinuses, middle ears, tonsils, pharynx, larynx, trachea or bronchi and even the lungs may be invaded Any of the potentially pathogenic micro-organisms present in the upper respiratory tract may lead to secondary infection

PATHOLOGIC PICTURE

The mucous membrane of the upper respiratory tract, especially that of the nose, is swollen and boggy and appears inflamed The lymphoid follicles in the affected area are somewhat enlarged There is a striking increase in secretion, both serous and mucous, from the nose Frequently, after some days purulent exudate appears on the surface of the turbinates and the walls of the nasopharynx In the early stages the nasal secretions contain relatively few cells or bacteria and may even appear to be sterile when cultured, later in the course of the disease considerable numbers of cells and various bacteria may be present The chief alterations are confined to the mucous membrane, vascular engorgement, edema and hypersecretion predominate, infiltration by lymphocytes and mononuclear cells occurs in mild degree, as does desquamation of surface cells; necrosis is usually absent

EXPERIMENTAL INFECTION, HOST RANGE

That bacteria-free filtrates of nasal secretions from patients with natural colds are capable of inciting experimental colds in man and the chimpanzee was demonstrated by Olitsky and McCartney (1923) and by Dochez et al (1930) The elaborate and extended investigation of Andrewes and his co-workers (Andrewes, 1949, 1950, 1953, 1958; Andrewes et al, 1951, Lovelock et al, 1952, Andrewes et al, 1953) with volunteers have demonstrated that small filterable agents present in the nasal washings of

Common Cold

(SYNONYMS Acute coryza, acute rhinitis)

INTRODUCTION

The common cold is widely recognized as a relatively mild and almost ubiquitous clinical syndrome which may be induced by one or more of several etiologic factors A considerable proportion of colds can be attributed to a viral infection of the upper respiratory tract. That there may be a number of viruses, each of which can incite the syndrome, seems probable Closely similar maladies which can be indistinguishable on clinical grounds are known to be induced at times by viruses which are associated with other disease categories such as influenza, acute respiratory disease and primary atypical pneumonia Some colds may not be induced by infectious agents but may arise from allergic or traumatic influences.

The symptoms and signs suggest that the syndrome results from an acute but transient alteration in the physiology of the mucous membrane of the upper respiratory tract, particularly that covering the nasal passages, the turbinates and the paranasal sinuses The syndrome develops in man more frequently than any other ailment and leads to an enormous total morbidity each year The incidence of colds is considered to be approximately 2 to 4 attacks per person per year Of themselves, colds are usually relatively mild disorders which generally do not linger for more than a week or two However, they may lead to secondary bacterial infections, especially of the paranasal sinuses, the middle ear, the larynx, the trachea and the bronchi, which may be protracted and occasionally are serious

HISTORY

The clinical syndrome was described in some of the earliest medical writings, and innumerable papers concerning it have appeared during the past several decades. Kruse, 1914, and Foster, 1916, were the first to report successful experimental transmission of colds with filtered material in man Numerous independent reports have appeared which confirm these early findings Dochez et al, 1930, first reported successful transmission of the common cold from man to chimpanzees by means of filtrates Cultivation in tissue-culture medium by Dochez et al (1931) and on the chorio-allantoic membrane of the chick embryo by Kneeland et al (1936) of a filterable agent capable of inducing colds in man has been described

The extensive investigations carried out with large numbers of human volunteers at the Common Cold Research Unit, Salisbury, England, since 1946 (Andrewes, 1949, 1950, 1953, 1958) have reaffirmed the infective nature of certain colds, the filterability of an inciting agent, and have provided much information on the transmission of colds from

virus or group of viruses. The agent is filterable through Berkefeld W candles and Seitz pads (Dochez et al., 1930). Studies with collodion membranes of graded porosity indicate that the agent may have dimensions of less than 70 mμ and possibly is as small as 30 mμ (Andrewes, 1949, 1953). It is not inactivated by penicillin or other antimicrobial agents but is inactivated in vitro by 20 per cent ethyl ether. It can be preserved and remains infectious for man for 2 years or more at −76° C. Conflicting results have been obtained in attempts to preserve the agent by freezing and drying in vacuo (Dochez et al., 1931, Andrewes, 1953).

As indicated above, the agent has not induced a recognizable infection in any species of laboratory animal tested, excepting only the chimpanzee (Dochez et al., 1930), and has not been propagated in series in any tissue culture system, excepting only cultures of human embryonic lung (Andrewes et al., 1953). In volunteers, after intranasal instillation of nasal washings secured from patients with natural colds, the incidence of experimental colds is about 50 per cent (Andrewes, 1949, 1953, 1958). Women appear to be slightly more susceptible to induced colds than men, the observed incidence in a very large series has been 55 per cent and 43 per cent, respectively (Andrewes, 1953). Neither age, between 18 and 40 years, nor the duration of the interval since the last cold nor the season of the year affected these rates appreciably. The most active nasal washings can be diluted as much as 1:1,000, but not 1:10,000, and will still produce colds in man.

The agent can be recovered from inoculated volunteers about 24 hours after intranasal instillation or approximately the same period before symptoms appear. This suggests that patients may be discharging the agent during the latter part of the incubation period as well as during the full-blown cold (Andrewes, 1950, 1953). How long the agent persists in the nasal secretions after a cold is not yet known, but it has been demonstrated in washings obtained as late as the 7th day. Whether the agent is present at times in the upper respiratory tract of apparently normal persons remains an open question. Because either pooled washings from normal persons or even normal embryonated egg materials have at times lead to the development of a cold on intranasal instillation in volunteers, this possibility has been considered (Andrewes, 1950).

No satisfactory serologic procedure has been devised with this agent and, as a consequence, it has not been feasible to carry out antigenic analyses or to make comparisons among various strains. Tests for immunity on second inoculation, either in man or in the chimpanzee, have not yet proved sufficiently satisfactory or reproducible to permit a study of the immunologic relations between different strains.

Serum from persons convalescent from colds may have the capacity to inactivate the agent, but it has not yet been established that this effect is produced by specific antibodies (Andrewes, 1950). The results of tests for immunity to second infection in chimpanzees suggest that some resistance develops and may persist for 3 or 4 months. The evidence regarding the possible development of resistance to second infection in man is not consistent. Pollard and Caplovitz (1948) reported that volunteers were refractory to infection on reinoculation for at least 13 days. On the other hand, the Commission on Acute Respiratory Diseases (1949) found no evidence of resistance to infection on reinoculation with the same nasal washings 19 to 21 days after the first inoculation. Andrewes (1950, 1953) has concluded that susceptibility to experimental colds in volunteers is not correlated with the time elapsed after the last cold.

Various groups of workers in the United States have reported that agents obtained from nasal secretions or washings of patients with colds could be passed in series in the chick embryo (Kneeland et al., 1936, Pollard and Caplovitz, 1947, Topping and Atlas, 1947, Ward and Proctor, 1950, Reagan et al., 1954, Pollard, 1956). The available data is not sufficient to support any conclusion regarding the relationship of these agents to each other or to the virus described by the British workers. Because of the uncertainties that continue to plague investigators in this field and the need to depend on elaborate and carefully controlled tests in volunteers before concluding that a cold-inducing agent is in

patients with colds can induce colds in about 50 per cent of test subjects when they are inoculated into the nasal passages. These agents have consistently failed to produce evidence of infection in a wide variety of animal species, including several species of primate, and it has not been possible even to demonstrate survival of the agents in their nasal passages (Andrewes, 1953). They could not be cultivated in embryonated eggs—in the yolk sac, the amniotic or the allantoic cavities—but in some instances did appear to survive in cultures of human embryonic nasal epithelium (Andrewes, 1953). One such agent was propagated through 10 serial cultures in human embryonic lung, in which it did not produce cytopathogenic effects, and remained capable of inducing colds in volunteers (Andrewes et al., 1953).

Cultivation of a cold-inducing agent in a tissue-culture medium has been reported by Dochez et al. (1931) and by Powell and Clowes (1931) In addition, an agent with similar capabilities has been cultivated on the chorio-allantoic membrane of the chick embryo by Kneeland et al. (1936). Several groups of workers in the United States have reported that agents from patients with colds could be cultivated in series in the allantoic sac of the chick embryo (Pollard and Caplovitz, 1947; Topping and Atlas, 1947; Ward and Proctor, 1950; Reagan et al, 1954; Pollard, 1956) These results clearly do not correspond to those secured during the same period by the British workers at the Common Cold Research Unit. Unequivocal explanations for the striking differences that have been reported are not yet available.

The induction of a coldlike infection in suckling hamsters has been reported by Reagan et al. (1956) but Jordan and Denny (1957) have reported that they were unable to transmit colds to these animals Reports of transmission to other small laboratory animals have not appeared

Price (1956) has described an agent, recovered from patients with coldlike symptoms, which produced cytopathogenic effects in monkey kidney cells in vitro and was transmissible in them in series. This agent did not cause degeneration of HeLa cells in culture and did not multiply in either the allantoic or the amniotic sac of the chick embryo. It did not produce evidence of infection in 1-day-old mice, 10-day-old hamsters, young guinea pigs, or ferrets.

Pelon et al. (1957) have reported the recovery of a cytopathogenic agents from adults with mild respiratory illnesses, many of which presented the clinical syndrome of the common cold. This agent also was transmissible in series in monkey kidney cells in vitro and caused destruction of epithelial cells. In addition, cytopathogenic effects were found in cultures of monkey testis and human embryo kidney but not in monkey cornea, chick embryo, HeLa, KB or human conjunctival cells This agent did not produce evidence of infection in the yolk, the allantoic or the amniotic sac of the chick embryo or in 1-day-old mice inoculated by several routes

ETIOLOGY

The concept that the clinical syndrome designated the common cold includes one or more specific disease entities induced by a virus is now widely accepted. The early and extended studies of Dochez and his co-workers (Dochez et al, 1930, 1931; Kneeland et al, 1936) provided the strongest support for this hypothesis that had been obtained up to that time. The more recent and even more comprehensive investigations carried out continuously since 1946 by the Common Cold Research Unit in England (Andrewes, 1949, 1950, 1953, 1958, Andrewes et al, 1951, 1953; Lovelock et al, 1952) have provided evidence that appears to be conclusive. Whether there is but one variety of common cold virus or a number of dissimilar viruses each of which can incite the same clinical syndrome, as in the case of influenza (cf. Chap 31), is not yet clear.

One of the major objectives of the British group of investigators was to use newer virus technics in attempts to discover a method of recognizing and titrating the cold virus or viruses with which they worked in the laboratory. This important objective has not yet been attained (Andrewes, 1953, 1958), and in consequence it has continued to be essential to conduct all definitive experiments in volunteers. As a result of carefully controlled tests in man the following facts have been established concerning the properties of this

upper respiratory tract, local irritations of the nose or the nasopharynx and a number of viral diseases in mild form, particularly influenza, acute respiratory disease, primary atypical pneumonia and abortive measles In addition, the rhinitis that is commonly associated with the onset of various other disease entities such as varicella, rubella and pertussis may closely simulate the common cold

TREATMENT

No clearly effective or specific method of treatment has been devised Symptomatic therapy appears not to alter significantly the course of the condition, although it often gives the patient some relief from the more distressing symptoms It has been claimed that various so-called antihistaminic drugs can be used as prophylactic or therapeutic agents Numerous carefully controlled studies, both in naturally occurring and in induced colds have failed entirely to affirm such claims (Feller et al 1950 Hoagland et al, 1950, Cowan and Diehl 1950 Medical Research Council, 1950 Shaw and Wightman 1951)

EPIDEMIOLOGY

The syndrome occurs throughout the world in every climate, and at any time There appear to be seasonal variations in incidence In the temperate zones the attack rate tends to rise during both the fall and the spring seasons In isolated Arctic communities the attack rate decreases markedly during the winter, the greater the degree of isolation, the lower is the incidence (Heinbecker and Irvine-Jones 1928, Paul and Freese, 1933) Re-establishment of contact with other communities often leads to a striking increase in the number of colds Whether this is attributable to the introduction of different strains of the causal agent or to a gradual decline in resistance to infection under conditions of isolation is not yet clear It is thought that the agent or agents are transmitted from one person to another under natural conditions, presumably by air-borne droplets However, attempts to induce contact infections under carefully controlled conditions have been surprisingly unrewarding (Andrewes, 1950, Andrewes et al, 1951, Lovelock et al, 1952). The idea that drafts and chilling tend to be associated with the development of colds seems to be firmly entrenched. Direct tests of the effects of chilling on susceptibility to experimental infection have failed to reveal any clear results (Andrewes, 1950)

Epidemiologic studies by Lidwell and Sommerville (1951) indicated that the probability of contracting a cold was about 1 in 5 when the infection was introduced into a household Adults in households in which there was a school-age child appeared to develop twice as many colds as others who lacked this close contact with children. Extensive investigations on respiratory infections in a group of families by Dingle and his co-workers (Dingle et al, 1949, Badger et al, 1953) indicate that respiratory diseases accounted for about 75 per cent of all episodes of illness and that some 40 per cent of respiratory illnesses were common colds.

CONTROL MEASURES

No effective control measures have been devised Various bacterial vaccines, designed presumably with a view to decreasing susceptibility to secondary bacterial infection, have been widely used, but carefully controlled studies have failed to provide evidence of a significant effect (Ferguson et al 1927, Diehl et al, 1938) Because of the lack of technics for the cultivation of viruses that are clearly associated with colds it has not been feasible to develop vaccines containing such viruses or test their possible efficacy Because of the apparent brief duration of immunity after either natural or experimental colds it has seemed probable that a vaccine of this kind might not be promising (Andrewes, 1953).

fact present, it is not yet possible to resolve the several conflicting results satisfactorily.

In addition to the agents indicated above, several new agents have been described in the past few years These agents all cause cytopathogenic effects in certain tissue culture systems and can be manipulated readily by the newer virus technics Further work will be needed before the extent of the relationship of any of them to the common cold becomes clarified The cytopathogenic agents recently reported by Price (1956) and Pelon et al (1957) appear to possess certain properties in common Both were recovered from patients with mild respiratory illnesses who showed syndromes that appeared to correspond with that of the common cold Both are transmissible in series in monkey kidney cell cultures and produce cytopathogenic effects Neither induces infection in HeLa cell cultures, chick embryo tissues or 1-day-old mice Both agents pass through filters that retain bacteria, and neither is inactivated by antimicrobial substances They are readily neutralized by convalescent sera of patients with homotypic disease, a definite neutralizing antibody response has been demonstrated by comparing the neutralization titers of acute phase and convalescent sera. Neutralizing antibodies against both agents were found with moderate frequency in the sera of children over 8 years of age and young adults Complement-fixing antibodies also were demonstrated with one of the agents (Price, 1946) but not with the other (Pelon et al, 1947) Hemagglutinating activity was demonstrable only with one (Pelon et al, 1947) Both agents were tested with numerous sera containing antibodies against a considerable number of other viruses and some rickettsiae In no instance was evidence obtained indicating an antigenic relationship between agents of established identity and these cytopathogenic agents There are as yet no published reports of cross immunologic tests with the two agents. However, on the basis of preliminary experiments Mogabgab (personal communication) considers that the two agents may be antigenically related, although they do not appear to be identical Apparently neither agent has as yet been tested directly in volunteers by the workers who recovered it to determine the clinical features of the experimental infection it might induce in man The JH virus (Price, 1956) after serial passage in monkey kidney cultures was tested in volunteers in England but appears not to have incited colds (Andrewes, personal communication). Recently, Price (1957) reported that an inactivated vaccine prepared with the JH virus protected children for several weeks against the overt illness due to this virus.

Cytopathogenic agents have been recovered by Sabin (cf. Ramos-Alvarez and Sabin, 1956) and by Morris et al (1956) from chimpanzees during outbreaks of naturally occurring mild respiratory illnesses simulating the common cold The chimpanzee rhinitis virus, which was recovered in 1954, appears to be related to ECHO type 10 virus (Sabin, 1956). The virus causes cytopathogenic effects in monkey kidney cultures and can be transmitted in series On nasal instillation it induced manifest rhinitis in chimpanzees which was associated with the development of neutralizing antibodies Antibodies against it have been demonstrated in man; although infants had none, children and young adults showed a progressively increasing incidence (Sabin, personal communication) The chimpanzee coryza agent (Morris et al, 1956) produced cytopathogenic effects in human liver cell cultures (Chang strain) and was propagated in series It appeared to be different from the rhinitis virus in serologic tests Antisera against a number of other viruses of established identity failed to react with the coryza agent A number of human beings, particularly adolescents and young adults, were found to have antibodies against the agent in their sera

DIAGNOSIS

The diagnosis is dependent entirely upon the clinical findings which in many cases are sufficiently characteristic to suggest the nature of the syndrome There is no laboratory test the results of which will positively support the diagnosis Many conditions may cause clinical syndromes closely similar to, if not identical with, that of the common cold, among these are various forms of nasal allergy, a variety of mild bacterial infections of the

CLINICAL PICTURE

The incubation period varies from 1 to 3 weeks, with an average of 12 to 14 days An exact clinical characterization of the disease is impossible because of lack of a specific diagnostic test, for it is likely that cases of mixed etiology have been included in past descriptions (Reimann, 1938 Dingle and Finland, 1942, Curnen et al, 1945, Jordan et al, 1951). However, since many of the cases were observed during epidemics and developed cold hemagglutinins, the pattern of illness woven from these descriptions probably does not represent too great a distortion of the manifestations of an entity

The onset is usually gradual and insidious The clinical features are those of a mild to moderately severe infection, and the early complaints may be referable to either the upper or the lower respiratory passages, or to both, or may be principally constitutional in nature Respiratory symptoms include throat irritation and cough, the latter being the most frequent and characteristic feature Constitutional symptoms include headache, malaise, feverishness, chilliness, fatigue and anorexia Headache is frequently an outstanding complaint and is particularly distressing when the patient coughs The cough is dry and frequently paroxysmal during the first 3 to 5 days of illness Ultimately, it is productive of sputum which is either mucoid or mucopurulent Blood-streaked sputum occurs in less than 10 per cent of cases A variable percentage of patients experience chest pain, which appears to be directly related to the severity of the cough, is substernal in location and is described as a burning sensation or aching discomfort In contrast to bacterial pneumonia, most patients do not appear very ill early in the disease, a shaking chill is rare, the pulse is slow in relation to the fever, respirations are normal or slightly increased; grossly bloody sputum and pleural pain are uncommon; herpes labialis is sel present

Examination usually reveals few striki abnormal physical signs Early in the cou the patient appears to be mildly or mo ately ill with little more than slight infl mation of the throat Minimal dullness percussion and diminution of breath sou may be present but seldom reflect the ex of infiltration demonstrated by roentg grams Early in the disease, the same is of rales Later, the most characteristic pl ical finding is the presence of fine, subc itant, sticky rales in the absence of sign true consolidation As the disease progres rhonchi or coarse rales may be heard

Roentgenographic examination often sh evidence of pneumonia before physical s are apparent, the disproportion between of infiltration and degree of pulmonary volvement demonstrated roentgenographic being an almost constant feature The c solidation usually appears to be most de at the hilum and is progressively less de near the periphery The borders of the pr monic lesions are irregular, and extens seems to occur in patchy fashion along course of the bronchovascular trunks shadows may appear diffuse, mottled, fea ery, or, in rare instances, dense The lo lobes are involved most frequently, altho any area in the lungs may be affected approximately 50 per cent of patients, pn monia is present in only one lobe Spread the infiltration, with resolution of the ea lesions as later ones appear, is not unc mon Thus, the changes are consistent w the concept that the infiltrative process one of peribronchial, peribronchiolar and terstitial inflammation, associated with fc atelectasis and edema The roentgenograp signs may be transitory for a few days may be progressive, they generally unde slow resolution over a period of 1 to 3 wee Residual nodular densities or prominent br chovascular markings may persist for seve weeks longer It is emphasized that the x-picture is not distinctive or diagnostic a is simulated by other forms of pulmon disease

Figure 103 illustrates the course of a c of average severity In this patient, con tutional symptoms, headache and cough w

Primary Atypical Pneumonia

(SYNONYMS Atypical pneumonia, virus pneumonia, acute interstitial pneumonitis)

INTRODUCTION

Primary atypical pneumonia is an acute, self-limited respiratory disease characterized by constitutional symptoms, cough, and pulmonary infiltration most readily demonstrated by roentgenogram Obviously, these characteristics are not specific, and similar clinical features may be manifested by certain viral and rickettsial diseases of established etiology, such as psittacosis and Q fever. Therefore, it is possible that more than one unknown agent may be responsible for infections classified as primary atypical pneumonia, accordingly, it has been customary to refer to the disease as a syndrome rather than as a specific entity Justification of this concept was obtained recently with the demonstration that pulmonary infiltration consistent with a clinical diagnosis of primary atypical pneumonia may occur in certain adenovirus infections (Chap 30) In such instances, however, pneumonia due to an adenovirus should be so diagnosed, rather than primary atypical pneumonia, just as a specific diagnosis of influenza is made when primary pneumonitis is found in that disease With the exclusion of known diseases which may present similar clinical syndromes, there emerges a form of pneumonia, often associated with the development of cold hemagglutinins, which appears to be an entity—primary atypical pneumonia.

HISTORY

The differentiation of primary atypical pneumonia from the bacterial pneumonias was accomplished in the late 1930's and early 1940's, but it is probable that some of the similar cases reported previously represented the same disease. Sections of lungs removed from soldiers during the Civil War

I also were instances of primary atypical pneumonia. Between 1930 and 1937, Arrasmith, Gallagher, Bowen, Allen, and Scadding reported cases in adolescents and young adults of pneumonitis characterized by a benign course and a lack of correlation between roentgenographic changes and physical signs In 1938 and 1939, Reimann, Smiley and others described similar cases and classified the disease as a new entity. Subsequently, with differentiation aided by the effectiveness of the sulfonamide drugs and penicillin in the bacterial pneumonias and the occasional epidemic occurrence of this nonbacterial disease, the clinical and epidemiologic features of primary atypical pneumonia were detailed by Kneeland and Smetana, Longcope, Dingle and Finland, and many others. During World War II, the disease occurred commonly, especially among military personnel, and the Commission on Acute Respiratory Diseases provided evidence re-

atypical

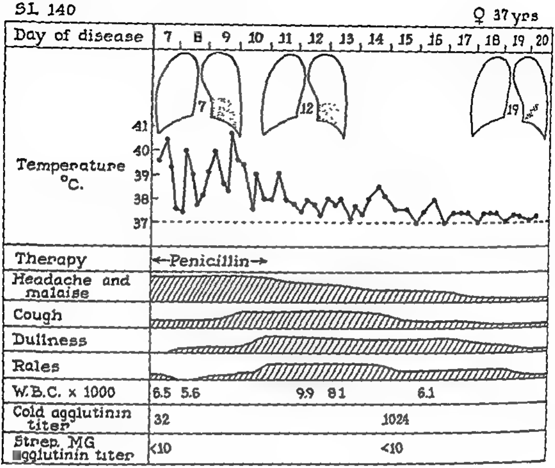

FIG 103. Chart of clinical findings in a case of primary atypical pneumonia

prominent, and at the time of hospitalization on the 7th day, there were no signs of consolidation and few rales despite demonstrable infiltration. Eventually, as happens in most instances, this discrepancy tended to disappear, and the extent of the physical signs became more comparable with the roentgenographic changes. As in the case illustrated, the majority of patients have normal total and differential leukocyte counts. The count may become elevated as the illness progresses, most often in association with spread of the infiltration in the absence of superimposed bacterial complications Erythrocyte counts and hemoglobin values are normal in uncomplicated cases. The sedimentation rate is elevated The urine is normal Culture of the sputum shows bacterial species normally found in the respiratory tract As noted subsequently, a variety of immunologic reactions occur with sera of convalescent patients, the most useful of which is the development of cold hemagglutinins. Occasionally, biologic false-positive Wassermann or Kahn reactions may be obtained.

The course of illness is extremely variable; the duration of fever and the degree to which the temperature is elevated range widely. Fever may be present for from 1 day to 6 weeks, it may be sustained but is most often remittent; it usually terminates by lysis in from 7 to 14 days. During the illness, headache, cough and sweating are commonly the most distressing symptoms. With extensive pulmonary infiltration, dyspnea, cyanosis and abdominal distension occur. In severely ill patients, the infection may aggravate or precipitate cardiovascular dysfunction, including auricular fibrillation, decompensation or circulatory collapse However, such an event is rare; accordingly, the case fatality rate is low (0 1 to 0.2%) (Dingle et al, 1944).

those of the naturally occurring disease and varied from mild respiratory infections to severe pneumonia Of 16 volunteers in whom pneumonia was induced, 13 developed 4-fold or greater increases in titers of cold hemagglutinins in their convalescent sera, and 2 also developed agglutinins against streptococcus MG. Of the 26 patients developing minor respiratory illnesses, without evidence of pneumonia, 11 developed cold hemagglutinins, and in 9 instances the increase was 4-fold The presence or the absence of streptococcus MG in the throat before and after inoculation had no relation to the development of pneumonia nor were there significant changes in the bacterial flora of the respiratory tract before, during or after the illnesses It is apparent that primary atypical pneumonia can be induced in volunteers by a filter-passing agent, presumably a virus, with the development of cold hemagglutinins and, in some instances, of agglutinins for streptococcus MG The results further suggest that the same agent may induce minor respiratory illness without pneumonic involvement

Many attempts have been made in a number of laboratories to transmit primary atypical pneumonia to animals and thus to define the host range of the causative agent or agents Sputa and throat washings obtained early in the course of the disease have been most commonly employed, in a few instances, pulmonary tissue from fatal cases has been used The commonest route of inoculation has been intranasal with the animals under light ether anesthesia Chick embryos have been employed, but thus far there are no reports of attempts using tissue culture The animal species used include the following mice, cotton rats, hooded rats, white rats, hamsters, guinea pigs, rabbits, 2 species of mongooses, 3 species of monkeys, baby chicks, ferrets, rice birds, doves, puppies, dogs, kittens, cats, young pigs and chimpanzees In a great majority of instances no evidence of infection has been found in the animals inoculated Several investigators have induced pulmonary lesions in animals by intranasal inoculation of sputum but have been unable to maintain the lesions on passage to additional animals or have found the same lesions in animals inoculated with control materials

Stokes et al (1939) reported transmission of the disease to mice, guinea pigs and ferrets, using material from 2 patients, but the infection could not be maintained in these animals on passage in the laboratory Weir and Horsfall (1940) reported transmission of the disease to the wild Jamaican mongoose, a finding which was not confirmed by the Commission on Acute Respiratory Diseases in collaboration with Dammin and Weller (1945) using the wild Puerto Rican mongoose Blake, Howard and Tatlock (1942) isolated a transmissible pneumotropic agent from cats ill in a household concomitantly with human cases of primary atypical pneumonia The agent could be transmitted to kittens, cats and hamsters Neutralization tests suggested that the feline and the human illnesses might have been due to the same agent However, later studies did not demonstrate a relationship between the feline agent and other human cases Other infections transmitted to animals have subsequently been found to be due to one of the psittacosis-lymphogranuloma group of viruses, herpes virus, or agents apparently latent in the animals employed (Eaton, 1950)

Eaton et al (1944) reported the production of pneumonic lesions in cotton rats and hamsters following primary intranasal inoculation of sputa and lung On serial passage, the lesions either disappeared or apparently were replaced by lesions due to contaminating or latent viruses The inoculation of chick embryos amniotically with filtered sputum failed to produce any evidence of infection, but lesions could be induced in cotton rats and hamsters inoculated intranasally with 20 per cent suspensions of chick embryo tissue The agent responsible could be maintained on repeated passage in chick embryos More recently, Liu (1957) has reported the transmission of infection to the chick embryo, using sputa and lungs from cases, as indicated in two ways by the fluorescent antibody technic and by the induction of pulmonary consolidation in cotton rats following intranasal inoculation with suspensions of chick embryo tissue Similar findings were obtained by Liu with the strain of virus isolated by Eaton in 1944 Mice and white rats are apparently not susceptible to infection, evidence regarding the guinea pig is indefinite

Resolution begins with return of the temperature to normal, and convalescence is usually uneventful except for asthenia.

Complications are uncommon, but involvement of nearly all organ systems has been reported. sinusitis, dermatitis, pericarditis, myocarditis, encephalitis, polyneuritis and thrombophlebitis Ulcerative tracheobronchitis may persist, but a residual of true bronchiectasis is apparently rare, although follow-up studies have not been carried out extensively enough to permit a reliable appraisal of residual complications Acute hemolytic reactions may occur in certain patients with high titers of cold hemagglutinins, an event usually induced by chilling. Secondary bacterial infection is very uncommon

PATHOLOGIC PICTURE

Relatively few patients in whom the diagnosis was well established have come to au-

al, 1947). Grossly, the lungs are heavier than normal, and areas of congestion and hemorrhage are apparent The pleural surfaces are usually normal but may show patches of fibrinous exudate Occasionally, small amounts of straw-colored pleural fluid are present The pneumonic areas may be extensive and widespread, or discrete, circumscribed and multiple Nodular focal lesions, resembling miliary granulomata, may be present. Various stages of consolidation, as well as areas of atelectasis and emphysema, are seen There is bronchitis and bronchiolitis, and the areas of infiltration are particularly prominent surrounding bronchi and bronchioles. The lumina of these structures contain tenacious exudate The bronchial mucosa is inflamed and ulcerated

Microscopically, the picture is one of interstitial pneumonia and necrotizing bronchitis and bronchiolitis (Fig. 104). The walls of the bronchi and the bronchioles show infiltration with mononuclear and polymorphonuclear cells which may extend into the peribronchiolar tissue and alveolar walls There is necrosis of epithelial cells with desquamation of the mucosa and ulceration The lumina contain this debris mixed with a purulent or mucoid exudate of mononuclear cells, neutrophils and fibrin

The alveoli show thickening of their walls, dilatation of the septal capillaries, edema in varying degrees, and infiltration of the septa by lymphocytes, mononuclear cells and erythrocytes The alveolar spaces may be air-containing, collapsed, or partially filled with exudate and edema fluid Bacteria usually are seen in the pneumonic areas The presence of intracellular inclusion bodies, elementary bodies, or rickettsiae has not been demonstrated

Pathologic alterations in other organs have been observed, particularly acute follicular splenitis, mesenteric lymphadenitis, focal hepatic necrosis, acute myocarditis and hemorrhagic encephalitis

EXPERIMENTAL INFECTIONS, HOST RANGE

The complex etiologic picture of primary atypical pneumonia, as indicated in the next section, renders difficult an orderly discussion of experimental infection and host range. There is no reason to doubt that man himself is susceptible, as indicated by the spontaneous occurrence of the disease and by its experimental transmission to volunteers However, the factor or factors responsible for induction of the spontaneous disease are not known It has been postulated that latent agents may be responsible, activated by some undetermined insult, such as a minor respiratory infection Such latent agents, as for example pneumonia virus of mice (PVM), have been found in a number of animal species and will produce pneumonia in the host animals after nonspecific provocation or after blind passage of suspensions of lung tissue There is no evidence either for or against the presence of similar latent viruses in the lungs of man.

The studies of the Commission on Acute Respiratory Diseases (1946) during World War II indicate that the disease can be transmitted and passed in volunteers under conditions suggesting a viral etiology. The volunteers inhaled a spray of sputa and throat washings obtained from patients and rendered bacteria-free by filtration Approximately 75 per cent of the recipients developed respiratory infections, and 25 per cent of them developed pneumonia, the incubation period being about 12 days. The illnesses resembled

section and described more fully in previous editions. The results of neutralization tests in animals with sera from a limited number of patients suggested that neutralizing antibodies had developed during convalescence. Perhaps the most significant of this latter group of agents is that isolated originally by Eaton et al. (1944) and more recently by Liu (1957). Eaton isolated the agent from approximately 50 per cent of the cases studied and demonstrated 4-fold or greater increases in neutralizing antibody titers in the convalescent sera of approximately 62 per cent of the total examined. Such increases were found most frequently in patients who also showed significant rises in cold hemagglutinins and in agglutinins for streptococcus MG. Using an ingenious, indirect fluorescent antibody technic, Liu studied the behavior of a strain of virus isolated by Eaton in 1944 and that of 8 strains isolated in Boston from sputum or nasal and throat washings, and of another strain isolated from the lung of a patient who died in 1943. Isolations could not be made with material from 11 additional cases. In most of these patients, there was an increase in the titer of cold hemagglutinins and of agglutinins for streptococcus MG in the convalescent sera. The technic consisted of sectioning the pulmonary tissue of chick embryos 5 to 6 days after amniotic inoculation, exposing the sections to antiviral, hyperimmune rabbit serum, or convalescent human serum, and tagging the antibody attached to the virus in the cells with the appropriate fluorescein-labeled antigamma globulin rabbit or human serum. The direct method of staining with fluorescein-labeled antiviral antiserum was not satisfactory because of the low intensity of specific fluorescence. By the use of the indirect technic, the virus was found only in the lower trachea, the bifurcation and the larger branches of the bronchi, and the air sac of infected chick embryos. No histopathologic changes were visible. No virus could be detected in the lungs of cotton rats showing pneumonia after intranasal inoculation of infected chick embryo material. All of the strains of virus isolated were antigenically similar. By this technic, a rise in titer of antibodies was demonstrated in the convalescent sera of 4 of the 8 patients from whom virus was isolated in Boston. Of the other 4 patients, 1, from whom no acute phase serum had been obtained, showed a titer of 1:320 in his convalescent sera, 1 had a titer of 1:160 in both the acute and the convalescent phase serum specimens, and from 2 no sera were available. No cross-reactions could be detected by this method with sera from patients with psittacosis, Q fever, adenovirus infections, or influenza A and B, or in anti-PVM rabbit serum. Liu concluded that the failure of other investigators to isolate Eaton's virus probably is due largely to the low pathogenicity of the virus and its lability. No data have yet been presented with respect to the ability of convalescent sera from cases of primary atypical pneumonia to neutralize Eaton's virus directly in embryonated eggs. Recently, Arakawa et al. (1956) have reported the isolation of a virus from the serum and the pleural fluid of patients with primary atypical pneumonia by intracerebral inoculation of mice and chorioallantoic inoculation of embryonated eggs. The agent apparently produces pneumonia in monkeys and is neutralized by the convalescent sera of patients.

The etiology of primary atypical pneumonia has not yet been clearly defined, and the picture remains confused. In all probability, more than one agent is involved. Final identification of the agent or agents must rest on isolation of the virus from clinically characteristic cases, demonstration of the appearance of antibodies to the agent in convalescent sera, neutralization of viral infectivity by antibodies in convalescent sera and in the sera of animals immunized with the isolated agent, correlation of the antibody level with resistance to infection and, ultimately, by experimental induction of the disease in volunteers or its equivalent. These criteria have not yet been fully met with any agent thus far reported as presumably responsible for the disease. In a general sense, cases resembling primary atypical pneumonia can be divided into 2 groups: (1) those that show the development of cold hemagglutinins or other peculiar serologic reactions, and (2) those that do not exhibit these phenomena. Some, but not all, of the latter group can be shown to be related to infections with psittacosis virus, the adenoviruses, or other agents. The former group may show not only

No other data are thus far available regarding the host range of the Eaton virus.

ETIOLOGY

As already indicated, the clinical features of primary atypical pneumonia are those of a syndrome that may be induced by a variety of infectious and noninfectious agents. Therefore, studies on etiology require a thorough clinical and laboratory investigation of the patient from whom specimens are obtained in order that the known causes of the syndrome can be excluded

Following the discovery of streptococcus MG, Thomas et al (1945) suggested the possibility that this organism might play a causative role. It was isolated from the lungs and the sputa of a number of cases in which no other etiologic agent was apparent. The various strains were serologically homogeneous The bacterium was agglutinated by the convalescent sera of from 35 to 50 per cent of cases of the disease. Thus the isolation of the organism and the development of antibodies in the sera of many patients during convalescence suggested that this streptococcus might be implicated etiologically—alone, or as a secondary invader, or in symbiosis with a virus The present evidence is insufficient to support this concept. The organism is not pathogenic and can be found in approximately 25 per cent of normal persons or patients with other respiratory infections. Pathologically, bacteria appear to have no appreciable part in the production of the lesions of primary atypical pneumonia The presence of streptococcus MG was not related to the experimental transmission of pneumonia in man. It seems most probable that the development of antibodies during convalescence is part of a nonspecific reaction similar to other peculiar nonspecific changes that occur in the sera of these patients during convalescence, or that streptococcus MG shares a common antigen with the causative agent of primary atypical pneumonia as in the case with certain strains of proteus and rickettsia (Weil-Felix reaction)

The results of the transmission studies of the Commission on Acute Respiratory Diseases (1946) summarized in the preceding section, indicate that the disease was at least initiated, if not caused, by a filter-passing agent, presumably a virus, and that the disease so transmitted was associated with the development of cold hemagglutinins In a subsequent study in volunteers (Commission on Acute Respiratory Diseases, 1947), it was found that there was no apparent relationship between primary atypical pneumonia, the common cold and acute respiratory disease (ARD) of recruits, as evidenced by differing clinical pictures, incubation periods, and lack of cross-immunity among the 3 diseases. With the discovery of the adenoviruses, it has been possible to re-evaluate these studies by examining the stored sera from donors and recipients for antibodies to the adenoviruses (Ginsberg et al, 1955). The results showed that the adenoviruses had not been related to these cases of primary atypical pneumonia or to the common cold, but that adenovirus type 4 had been responsible for the cases of acute respiratory disease (ARD).

The results of many attempts to isolate an infectious agent in laboratory animals and to demonstrate its etiologic relationship to the human disease have been conflicting and difficult to interpret. Some of these attempts with materials from both endemic and epidemic cases have been entirely unsuccessful. Adams et al. (1942, 1945) failed to isolate a virus in his studies of 3 epidemics of pneumonitis in infants. However, these outbreaks may have been caused by a different agent, as suggested by the presence of inclusion bodies found at autopsy. Similar inclusion bodies have not been demonstrated in the lungs of adults Other studies have resulted in the isolation of known viruses, such as psittacosis and herpes, or of viruses which clearly were not related to the human disease or were derived from the animals employed. In addition, a virus has been isolated which was termed the newborn pneumonitis virus, type Sendai (Kuroya and Ishida, 1953) and later was classified with the influenza group and designated influenza virus D (Jensen et al, 1955).

Still other investigations have yielded agents that produced what appeared to be infectious processes or lesions in the chick embryo, the hamster, the cotton rat, or the mongoose, as mentioned in the preceding

of cases of psittacosis, Q fever, adenovirus infections and influenza

The significance of the various immunologic reactions that may be obtained with convalescent sera is not clear. Cold hemagglutinins and agglutinins for streptococcus MG appear to be different antibodies, since each can be removed separately by adsorption of a serum containing both of them without appreciably affecting the titer of the other In addition, each may appear independently Both of them are distinct from the antibody for Eaton's virus Other unusual immunologic reactions may also be demonstrated with convalescent sera, such as false-positive serologic tests for syphilis, fixation of complement with fresh tissue antigen of various sorts, and the prevention of development of antibodies to pneumonia virus of mice (PVM) It is entirely possible that all of these are nonspecific reactions dependent in some fashion on the breakdown of pulmonary tissue or on the pulmonary infection

The differential diagnosis requires consideration of a number of infectious and noninfectious diseases that may present a similar or even identical clinical picture Among the bacterial diseases, tuberculosis, tularemia and typhoid should be considered Most of the cases of bacterial pneumonia can be distinguished readily on clinical grounds, but about 5 to 10 per cent of cases in adults and children will present differential problems Of the fungus infections, coccidioidomycosis and histoplasmosis are most apt to cause difficulty, since these infections frequently occur without concomitant cutaneous involvement A history of residence in an endemic area is helpful in these cases Most of the rickettsial infections except Q fever can be differentiated by the presence of an eschar or the development of a rash However, Q fever may closely resemble primary atypical pneumonia, although in general the onset is more sudden, constitutional symptoms predominate throughout the illness, respiratory symptoms are minimal, and the roentgenographic evidence of infiltration is usually more focal in character and more apt to appear in the lung parenchyma without hilar involvement Although pulmonary infiltration may occur in such contagious diseases as measles and chickenpox, the commonest viral diseases that should be considered in differential diagnosis are those due to the psittacosis group of viruses, the influenza viruses including newborn pneumonitis virus, type Sendai, the virus of lymphocytic choriomeningitis, and the adenoviruses, particularly those types (4 and 7) that most frequently cause acute respiratory disease (ARD) of recruits An epidemiologic history of exposure to birds or mice suggests the possibility of psittacosis or lymphocytic choriomeningitis. Cases due to one of the influenza viruses or to adenoviruses are most apt to occur during epidemics of these diseases Rarely, toxoplasmosis and ascariasis or other parasitic diseases must be considered in the differential diagnosis

In general, the final diagnosis of the above infections can be established by isolation of the infecting agent, by the demonstration of a rise in serum antibodies during convalescence, or by both procedures Further differential features of the viral and rickettsial diseases that may present difficulty are discussed in other chapters of this book and will not be considered further here

Noninfectious processes resembling primary atypical pneumonia, such as bronchiectasis, eosinophilic pneumonia or Loeffler's syndrome, sarcoidosis carcinoma, atelectasis and infarction usually can be recognized and differentiated by clinical and laboratory procedures and the course of illness

TREATMENT

Symptomatic and supportive treatment forms the basis for the management of patients with primary atypical pneumonia As in other infectious diseases, bed rest, good nursing care, a palatable diet suited to the patient's desires, and adequate parenteral or oral fluids are important Drugs or procedures such as Neo-synephrine, codeine, dihydrocodeinone, oxygen and postural drainage may be helpful Antipyretic drugs with a diaphoretic action, such as acetylsalicylic acid, should be avoided if sweating is a prominent feature. Sponge baths with cool water or alcohol should be avoided in severely ill patients, because a hemolytic crisis may be induced if the titer of cold hemagglutinins in the patient's serum is high. Sedation and transfusion may be employed if indicated.

the development of cold hemagglutinins but also agglutinins for streptococcus MG, complement-fixing antibodies for a variety of antigens, and other peculiar behavior Horsfall et al (1943), for example, showed that sputum from 1 patient with primary atypical pneumonia, when inoculated intranasally in cotton rats, induced pulmonary consolidation and stimulated the development of neutralizing antibodies for pneumonia virus of mice (PVM) and that mixing the sputum with convalescent sera from human cases could prevent both the development of pneumonia and such antibody production The variety of reactions occurring in the sera of patients suggests that antibodies of several sorts may be induced nonspecifically in some manner as yet unknown Thus it may be that the agent isolated by Eaton and by Liu and the antibody reactions to it demonstrated by the indirect fluorescent antibody technic represent still another example of a peculiar reaction not necessarily dependent solely on the specific etiologic agent Further studies and data are necessary before the puzzling etiology of primary atypical pneumonia is clarified.

DIAGNOSIS

The diagnosis of primary atypical pneumonia is based on a process of exclusion, since direct confirmation is not now possible by means of a practical and specific laboratory procedure utilizing the causative agent. Two serologic tests have been used extensively as retrospective aids in diagnosis· cold hemagglutination and agglutination of streptococcus MG The technics are described in Chapter 10, "Serologic Reactions in Viral and Rickettsial Infections" Both tests are best performed with acute-phase serum specimens obtained during the first week of illness and convalescent-phase specimens obtained 3 or 4 weeks after onset If either or both types of agglutinin appear in the convalescent sera, and especially if a 4-fold or greater increase in titer is demonstrable some weeks after onset, there is a high probability that the diagnosis is correct The absence of these agglutinins does not exclude the diagnosis but makes it more difficult to establish

Cold hemagglutinins for group O human erythrocytes appear in the convalescent sera of approximately 50 per cent of the patients, with variations in different series of cases from about 30 per cent to almost 100 per cent. Maximum titers are usually reached in the 3d or the 4th week after onset, following which a decline occurs during the succeeding 2 or 3 weeks. Agglutinins for streptococcus MG have been reported in some 20 to 75 per cent of cases. These agglutinins usually appear in the 2d or the 3d week after onset, reach their maximum titers in the 4th or the 5th week and begin to decline in the 7th or the 8th week There is a positive correlation between the frequency with which both of these agglutinins develop and the severity of the disease, the extent of pulmonary involvement and the duration of illness A similar correlation is found in the height of the titers reached.

The indirect fluorescent antibody technic of Liu (1957), using the Eaton virus, may also be employed with acute-phase and convalescent sera to substantiate the diagnosis, although sufficient numbers of cases have not yet been studied to give an indication of the frequency with which a positive reaction will occur This technic may also be employed to detect the presence of the Eaton virus in chick embryos inoculated with sputum or throat washings obtained from patients during the acute phase of their illnesses, and the results may be determined within a week after inoculation of the eggs However, the technic is highly specialized, and it is unlikely that it will be utilized in more than a few medical centers for some time to come The value of any of the above tests in the management of the patient is obviously limited, since the acute phase of the illness, when decisions regarding therapy must be made, will be over in most instances before the results of the tests are known

Apart from primary atypical pneumonia, cold hemagglutinins may be found in patients with trypansomiasis and occasionally in patients with malaria, blood dyscrasias, or liver disease Agglutinins for streptococcus MG are rarely found except in patients with primary atypical pneumonia The specificity of the new fluorescent antibody test for Eaton's virus has not yet been adequately determined, but no such antibody has been detected in the convalescent sera of a limited number

and by transmission studies in man. However, such a relationship cannot be confirmed until specific diagnosis and detection of all cases are possible The incidence of the disease usually rises during the winter months, so that an etiologic relationship between this disease and other respiratory infections may be more apparent than real All age groups are attacked. The degree and the duration of immunity following infection are not known, but second attacks have been observed

CONTROL MEASURES

No specific prophylactic measure is available. With the sporadic cases, case-to-case spread is rarely apparent, and isolation of the patients is seldom practiced Isolation precautions may be helpful in the event of a spreading outbreak

Complications should be treated as they arise. Secondary bacterial infection occurs extremely rarely, when it does, it is accompanied by a dramatic change in the clinical condition of the patient, evidenced by manifestations of sepsis such as spiking fever, prostration and elevation of the leukocyte count Therapeutic agents should be selected in accordance with the sensitivity of the infecting bacterium Convalescence may be prolonged due to asthenia and slow resolution of the pulmonary infiltration, but activity need be restricted only to the tolerance of the patient

A variety of substances have been employed in the search for a specific therapeutic agent for this disease However, interpretation of the results has been difficult, not only in individual cases but also in controlled studies because of the variation in the course of the disease from patient to patient. The sulfonamide drugs, penicillin and streptomycin are now considered to be without beneficial effect The situation with respect to the so-called broad-spectrum antibiotics, such as the tetracyclines and chloramphenicol, is not so clear, and there are several conflicting reports regarding their efficacy. Many of the reports are based on dramatic improvement in individual patients after administration of a drug Other studies comparing treated and untreated groups or control groups given penicillin have shown apparently beneficial results in some series but not in others (Tillotson and Oseasohn, 1952, Finland, 1952). It may be that the same diseases were not being treated in the different studies, as perhaps is indicated by the fact that differing proportions of the patients in the various series have shown the development of cold hemagglutinins. Meiklejohn et al (1954) have reported that patients who have severe illnesses with temperatures above 102° F. are benefited to the greatest extent but that similar benefit is not observed in the milder cases. Whether this result is due to a specific action of the antibiotic on the virus or to an antipyretic action (Tillotson and Ginsberg, 1954) has not yet been clearly established In this respect it is interesting that streptococcus MG is resistant to sulfonamide drugs but is susceptible to penicillin and chlortetracycline. The virus of Eaton is resistant to penicillin and chloramphenicol but is susceptible to streptomycin and chlortetracycline These findings do not appear at present to be compatible with the evaluations of therapy in patients.

In view of the rarity of secondary bacterial infections, the prophylactic use of any chemotherapeutic agent during the course of the illness is not warranted

EPIDEMIOLOGY

The disease occurs throughout the world, usually in endemic form. Its epidemic occurrence in both civilian groups (Gallagher, 1934, Reimann, 1938; Kneeland and Smetana, 1940; Favour, 1944, Jordan, 1949), such as hospital personnel and families, and in military populations (Campbell et al, 1943; Dingle et al, 1944) has been described frequently and was one of the factors responsible for the recognition of this form of pneumonia. Yet few epidemics have occurred in recent years, and the cases observed since 1948 have been small in number and mild in nature Since the distribution of antibody to the etiologic agent in the general population cannot yet be measured, past behavior of the disease is crudely defined, and the likelihood of future epidemics is totally unpredictable.

The true incidence is not known. Among armed forces personnel during World War II, the attack rate averaged 10 per 1,000 per year, about 10 times the incidence of bacterial pneumonia In some epidemics, attack rates as high as 15 to 20 per cent have been reported, and in one study of multiple cases in families a rate of 35 per cent was noted (Jordan, 1949). Case-to-case spread has been apparent in such instances, and the epidemiologic behavior has suggested a relationship between degree of contact and contagiousness The mechanism of transmission appears to be through direct contact with infected persons These inferences are supported by the results of studies in volunteers (Commission on Acute Respiratory Diseases, 1946) which indicated that the infection may be transmitted by respiratory secretions and that the portal of entry is the upper respiratory tract The duration of the period of communicability is unknown

An etiologic association between primary atypical pneumonia and certain minor respiratory illnesses has been suggested by the sequence of occurrence of cases in epidemics

and by transmission studies in man However, such a relationship cannot be confirmed until specific diagnosis and detection of all cases are possible. The incidence of the disease usually rises during the winter months, so that an etiologic relationship between this disease and other respiratory infections may be more apparent than real All age groups are attacked The degree and the duration of immunity following infection are not known, but second attacks have been observed

CONTROL MEASURES

No specific prophylactic measure is available With the sporadic cases, case-to-case spread is rarely apparent, and isolation of the patients is seldom practiced Isolation precautions may be helpful in the event of a spreading outbreak

The Adenovirus Group

INTRODUCTION

The adenovirus group is composed of at least 23 immunologically distinct types of viruses that are related by a common complement-fixing antigen and possess the properties of ether resistance, stability to temperature and pH changes, lack of pathogenicity for laboratory animals, and multiplication in a number of lines of epithelial or epithelial-like cells in tissue culture. To date 18 types have been isolated from human and 5 from simian sources. Certain of these agents, particularly types 3, 4 and 7, have been associated with both epidemics and sporadic cases of respiratory disease. The type 8 virus appears to be the major causative agent of epidemic keratoconjunctivitis. Numerous types have been isolated from surgically removed tonsils and adenoids, some of these types have not yet been shown to cause disease

HISTORY

The first isolations to be reported were made by Rowe et al. (1953) from fragments of human adenoids grown in tissue culture After prolonged incubation cytopathic change was noted in the epithelial-like cells of some of the cultures and passage revealed the presence of virus A large number of strains, principally of types 1, 2 and 5, have since been obtained from cultures of both tonsils and adenoids when grown under similar conditions These agents, initially called *adenoid degeneration* or *AD* agents, had no apparent relation to respiratory disease. Almost simultaneously, Hilleman and Werner (1954) isolated by tissue culture technics a cytopathogenic agent from army recruits sick with an influenzalike or grippelike illness. An increase in neutralizing and complement-fixing antibodies against the virus was shown to occur in the patients Previously, this disease had been described by several investigators as an important problem in military forces and had been variously termed catarrhal fever, febrile catarrh and acute respiratory disease of recruits (ARD). During World War II the Commission on Acute Respiratory Diseases (1947a, b, c) presented evidence that acute respiratory disease (ARD) was a distinct clinical entity caused by a virus Retrospective studies employing sera still available from the Commission's volunteer experiments in 1947 indicated that the virus isolated by Hilleman and Werner (designated *RI-67*) was identical with or immunologically closely related to the virus which was transmitted to the volunteers (Ginsberg et al , 1955a) [illegible]

[illegible] Ginsberg et al , 1955b)

Huebner et al (1954) showed that at least 6 immunologically distinct types of virus existed, all related by a common group-specific complement-fixing antigen, and suggested the name adenoidal-pharyngeal-conjunctival (APC) viruses for the group The RI-67 virus isolated by Hilleman and Werner was demonstrated to be a member of

mal limits, and no abnormalities are found in the urine Cultures of the throat or of the sputum, if available, reveal only the normal bacterial flora of the respiratory tract The febrile course is short, generally lasting from 2 to 4 days The fever may reach levels of 103° to 104°, but the average maximum temperature is about 100° F The fever may subside abruptly or by lysis. Constitutional symptoms subside with defervescence, but symptoms referable to the respiratory tract, when present, tend to persist for from 1 to 2 weeks Recovery is uneventful and complete, and bacterial complications have not been described among hospitalized patients

PHARYNGITIS AND PHARYNGOCONJUNCTIVAL FEVER

(SYNONYMS Nonbacterial pharyngitis, nonstreptococcal exudative tonsillitis and pharyngitis)

The clinical picture of pharyngitis and pharyngoconjunctival fever due to the adenoviruses is remarkably similar to that described above for acute respiratory disease (ARD) when exception is made of those symptoms and physical signs which are related to the local inflammation in the throat and in some cases of the eye The incubation period is estimated to be 5 to 7 days (Bell et al, 1955) The onset is gradual in about 80 per cent of the cases The illness is characterized by fever, sore throat and in some patients by conjunctivitis The symptoms of feverishness, chilliness, headache, anorexia, sore throat, hoarseness and cough are present in about three fourths of the patients Malaise is not uncommon In less than half the patients the cough may be associated with sputum and dull substernal chest pain On physical examination the patients appear to be acutely but not seriously ill Fever is usually present, and the pulse rate is elevated in accordance with it When present, conjunctivitis is mild and follicular in type and may be unilateral or bilateral Nasal obstruction and slight coryza are not uncommon The pharynx may be normal or moderately red, and lymphoid hyperplasia is common Exudate may or may not be present on the posterior pharyngeal wall and on the tonsils When present it is not extensive, is often pinpoint, grayish white in appearance and frequently is confined to the pharyngeal wall Redness and edema of the palate and petechiae may rarely be found. Moderate cervical lymphadenopathy may be present and in patients with conjunctivitis there may be nontender, preauricular lymphadenopathy. The total leukocyte count may be normal or slightly elevated but rarely exceeds 12,000 cells per cu mm The differential count may show a mild neutrophilia The urine is normal, and cultures of the throat reveal the common respiratory tract flora During the acute stage of illness virus may be isolated from the throat and when conjunctivitis is present, from the conjunctivae

The febrile illness is seldom longer than 4 or 5 days in duration The fever is sustained and sometimes attains levels of 103° or 104° F The average peak of temperature is between 101° and 102° F, and the fever ordinarily declines by lysis Sore throat and constitutional symptoms predominate at the onset, with other symptoms referable to the respiratory tract becoming more prominent as the illness progresses Sore throat is generally mild Nausea, vomiting, diarrhea, epistaxis and transient hepatomegaly have been noted rarely When conjunctivitis is present, it may last for a few days to 3 weeks Photophobia and retro-orbital pain have not been associated with the conjunctivitis, although corneal opacities have been reported (Cockburn et al, 1956, Ormsby and Aitchison, 1955) Otitis media may occur as a complication or as part of the disease Recovery is complete without sequelae, and no fatalities have been reported Illnesses similar to the spontaneously occurring disease have been induced by the inoculation of volunteers In view of the fact that various types of adenovirus may be isolated from tonsillar and adenoidal tissue removed surgically, Huebner et al (1954) have postulated that these agents may cause a low-grade chronic infection of the adenoidal tissue leading to hypertrophy Sufficient data are not yet available to substantiate this view

CONJUNCTIVITIS AND KERATOCONJUNCTIVITIS

Follicular conjunctivitis, caused by one of several types of adenovirus, may occur as the

this group and was assigned the designation type 4. In addition, an agent isolated by Neva and Enders (1954) was shown to be a strain of type 3. Due to the differences in nomenclature employed by the various laboratories studying these viruses, a group of interested investigators met and agreed upon the name *Adenoviruses* (Enders et al., 1956) as being generally acceptable and in accordance with the recommendations of the Subcommittee on Viruses of the International Nomenclature Committee.

With time, excellent clinical, epidemiologic and laboratory data have accumulated to indicate that type 3 virus is a frequent etiologic agent of nonbacterial pharyngitis with or without conjunctivitis (Parrott et al., 1954; Bell et al., 1955; Ginsberg et al., 1955b, Cockburn et al., 1956; Jawetz et al., 1956), that types 4, 7 and 14 are responsible for acute respiratory disease (ARD) (Hilleman et al., 1955d, Berge et al., 1955, Andrews et al., 1956, Dascomb and Hilleman, 1956, Rowe et al., 1956a, van der Veen and Kok, 1957) and for some cases of nonbacterial pharyngitis, and that type 8 virus is probably the causative agent of epidemic keratoconjunctivitis (Jawetz et al., 1955a) Type 8 adenovirus is not immunologically or biologically related to St Louis encephalitis virus, an agent closely related to or identical with that reported by Sanders and Alexander (1943) to be the etiologic agent of epidemic keratoconjunctivitis (Cheever, 1951, Ruchman, 1951). Since neither the original viruses nor the sera from the patients studied by Sanders and Alexander are available, it probably will not be possible to compare the type 8 adenovirus with the agent isolated by these workers.

CLINICAL PICTURE

The clinical picture of infections caused by the adenoviruses can be presented most conveniently here as comprising 3 syndromes: (1) acute respiratory disease (ARD), occurring almost exclusively in military recruits and caused predominantly by types 4 and 7, (2) pharyngitis and pharyngoconjunctival fever, caused principally by type 3, and (3) conjunctivitis and keratoconjunctivitis, caused primarily by types 3 and 8, respectively. However, there is considerable overlapping in the syndromes, so that one type of virus may cause an illness resembling acute respiratory disease in one patient and conjunctivitis or pharyngoconjunctival fever in another. This variation is particularly evident in sporadic cases, whereas the clinical picture is more consistent in epidemics. It should be emphasized that these clinical entities may also be caused by other agents and so are not necessarily specific for the adenovirus group.

ACUTE RESPIRATORY DISEASE (ARD)

(SYNONYMS: Febrile catarrh, acute respiratory disease of recruits, catarrhal fever, common respiratory disease)

This disease, which has been described almost exclusively in military recruits, is usually a relatively mild, grippelike illness. The incubation period, as indicated epidemiologically and from transmission studies in volunteers, is from 5 to 6 days. Ordinarily, the onset is gradual over a period of 2 to 3 days, but occasionally it may be abrupt. Feverishness and chilliness are the outstanding constitutional symptoms and usually are accompanied by headache, malaise and anorexia. Symptoms referable to the respiratory tract may appear early but generally are less prominent than the constitutional symptoms. Nasal obstruction and occasionally slight nasal discharge occur in approximately half of the patients. Irritated or sore throat is common but is mild in degree. Minimal hoarseness and dry cough are common, although fewer than half the patients have a productive cough or pain in the chest. On physical examination the patient appears to be acutely but rarely severely ill. Physical signs may be few or absent and usually are noted in less than half the patients. Nasal obstruction, mild injection of the pharynx and the palate, and lymphoid hyperplasia on the pharyngeal wall are found most frequently. Edema of the mucous membranes and mild cervical adenopathy are present in approximately 10 per cent of the patients. Pulmonary rales and roentgenographic evidence of infiltration of the lungs may be found in approximately 10 to 12 per cent of the patients, particularly during epidemics. The pulse rate is ordinarily compatible with the temperature, and the respiratory rate is normal. Total leukocyte and differential counts are usually within nor-

formation of type-specific antibodies following intranasal inoculation of a small dose of virus The animals to which adenovirus infection could not be transmitted were infant and adult mice, and infant hamsters inoculated by intranasal, intraperitoneal, intracerebral and intravenous routes, adult guinea pigs inoculated intraperitoneally and intranasally as well as on the cornea and in the anterior chamber of the eye, adult cotton rats by intracerebral and intranasal routes, on the conjunctiva and in the cornea, white rats inoculated intracerebrally and intranasally, rhesus monkeys inoculated intracerebrally, intranasally and subcutaneously, kittens inoculated intracerebrally adult ferrets inoculated by the intracerebral, the intraperitoneal and the intranasal routes and embryonated chicken eggs inoculated into the yolk, the allantoic and the amniotic sacs However, tissue culture technics offer a large number of cell lines which support multiplication of adenoviruses and respond to infection with characteristic cytopathic changes HeLa cells epithelial-like cells derived by Grey from an epidermoid carcinoma of the cervix, have proved to be most generally useful for propagation of adenoviruses In addition these agents multiply and induce cytopathic changes in a variety of other epithelial-like cell lines derived from several types of cancer, human conjunctival membrane nasal mucosa, bone marrow, tonsils, adenoids, liver and intestine, and maintained in continuous culture Adenoviruses will also multiply in tissue cultures prepared from human tracheal epithelium, human amnion, monkey and rabbit kidney and rabbit tracheal epithelium Undoubtedly many other susceptible cells have been employed, or will be found to support multiplication of these agents Although epithelial cells appear to be most susceptible to infection, fibroblasts in mixed cultures also are affected eventually Whether adenoviruses propagate in these cells or damage the fibroblasts by a toxic action has not been determined

The only animal shown to be readily susceptible to adenovirus infection is man The Commission on Acute Respiratory Diseases (1947b, c) produced acute respiratory disease (ARD) by inhalation of a spray of filtered respiratory secretions from a characteristic case of acute respiratory disease (ARD). Subsequent studies indicated that the virus transmitted was identical with or immunologically closely related to type 4 virus (Ginsberg et al, 1955a). When inoculated intranasally into volunteers, type 1, 2, 3 or 4 adenovirus, previously passed in HeLa cells, resulted in the formation of neutralizing and complement-fixing antibodies but not in the production of clinical respiratory disease (Bell et al, 1956b, Southam et al., 1956) On the other hand, type 1 virus propagated in embryonic human kidney cells, when inoculated intranasally, produced pharyngitis in 2 of 4 volunteers who had no pre-existing neutralizing antibodies (Roden et al, 1956) When virus which had been grown in monkey kidney cells was rubbed on the conjunctiva, moderately severe catarrhal conjunctivitis and pharyngitis accompanied by systemic symptoms resulted (Bell et al, 1956b) Adenovirus type 4 or 7 injected intramuscularly by Hilleman et al (1957b) induced fever, constitutional symptoms and the production of antibodies, but multiplication of virus was not demonstrated Type 8 virus, when instilled into the conjunctival sac after scraping of the conjunctiva or the cornea, resulted in follicular conjunctivitis, keratitis and corneal opacities characteristic of epidemic keratoconjunctivitis (Mitsui et al, 1957, Bietti and Bruna, 1957), and infection spread to susceptible contacts However, instillation of type 8 virus without injury to the conjunctiva or the cornea did not initiate disease.

At least 5 serologic types are apparently of simian origin Four of these types were obtained from monkeys, and one was isolated from the stool of a chimpanzee with a mild upper respiratory disease (Rowe et al, 1956b, 1958) It has not yet been determined whether disease can be initiated in monkeys or chimpanzees by inoculation of these types

ETIOLOGY

The adenovirus group is composed of a number of viruses related by a common complement-fixing antigen and many similar biologic properties Although the small antigenic particles detected by complement-fixation technics are immunologically similar but probably not identical for all viral types

only manifestation of infection or, as indicated above, may be associated with involvement of the respiratory tract and with systemic manifestations. Involvement of one or both eyes may occur and is manifested by redness of both the bulbar and the palpebral conjunctivae. Excess lacrimation, serous exudation and occasionally edema may occur. Other manifestations of ocular disease are usually lacking, although corneal opacities have been reported (Cockburn et al., 1956, Ormsby and Aitchison, 1955). The clinical disease has been reproduced in volunteers by swabbing the lower palpebral conjunctivae with adenovirus types 1, 3, 4 and 5 (Bell et al., 1956b). Conjunctivitis developed within 2 to 7 days and persisted for varying periods of time up to 3 weeks. Preauricular lymphadenopathy, which may or may not be tender, is commonly found. Recovery is complete without sequelae.

The clinical picture of epidemic keratoconjunctivitis is now becoming clarified by recent evidence that the disease is associated with or caused by adenovirus type 8 (Jawetz et al., 1955b; 1957). The incubation period of the naturally occurring infection is unknown, but it has averaged 5 to 7 days in volunteers inoculated with material from patients with the disease (Aoki and Kasahara, 1941) or with type 8 virus grown in tissue culture (Mitsui et al., 1957). The onset is sudden, with redness and chemosis of the conjunctiva and edema of the periorbital tissues. Exudate may be absent or may be serous or seromucoid in character. Constitutional manifestations of low-grade fever, headache and malaise may be present. Initially, the disease is ordinarily unilateral, but in about half the patients the other eye becomes involved 3 to 7 days later. Within 2 to 4 days after onset, preauricular lymphadenopathy develops and is usually tender. Small, round, superficial opacities of the cornea are noted within 4 to 14 days after onset. Ulceration of the cornea does not occur. In severe cases these lesions may coalesce. The duration of illness is from 2 to 4 weeks, and complete recovery occurs in most patients. However, keratitis with impairment of vision may persist in from 1 to 10 per cent of the patients.

PATHOLOGIC PICTURE

Deaths as a result of the most common adenovirus infections have not been reported. Hence, the pathology of acute respiratory and ocular infections, with the exception of epidemic keratoconjunctivitis, has not been described. However, 2 fatal cases of nonbacterial pneumonia in infants from which adenoviruses were isolated have been reported (Drouhet, 1957; Chany et al., 1958). From one of these, type 7a virus was isolated (Chany et al., 1958). The exact role of the adenovirus in the causation of the marked pulmonary consolidation cannot be assessed. However, a striking finding in the bronchi and the alveolar walls was the presence of numerous epithelial cells in which the nuclei were enlarged and contained a central basophilic mass surrounded by a vacuolated area. In some cells the intranuclear inclusion appeared to be eosinophilic. The nuclear changes observed were very similar in appearance to the rosette form of the late stages of cytologic alterations described in adenovirus-infected cells in culture (Barski, 1956; Boyer et al., 1957a).

Epidemic keratoconjunctivitis is characterized by marked edema of the conjunctivae followed by an exudate of mononuclear cells, chiefly lymphocytes. These cells, along with epithelial cells, may be seen in smears and scrapings from the conjunctivae. On the third to the fifth day of disease a pseudomembrane containing many mononuclear and degenerating epithelial cells may cover the conjunctivae. On about the sixth to the eighth day small opacities appear beneath the epithelium but do not involve this cell layer. For this reason the opacities are not stained by fluorescein. The lesions neither ulcerate Bowman's membrane nor do they become vascularized.

EXPERIMENTAL INFECTION, HOST RANGE

Man is the natural host for most types of adenoviruses, and extensive attempts to produce disease in a wide range of common laboratory animals have failed. There is suggestive evidence that infection can be induced in chimpanzees and Syrian hamsters (*Cricetus auratus*) by intranasal inoculation, but serial transmission has not been accomplished, nor have lesions been produced in either host. In these animals, the criterion for infection was

formation of type-specific antibodies following intranasal inoculation of a small dose of virus. The animals to which adenovirus infection could not be transmitted were: infant and adult mice, and infant hamsters inoculated by intranasal, intraperitoneal, intracerebral and intravenous routes, adult guinea pigs inoculated intraperitoneally and intranasally as well as on the cornea and in the anterior chamber of the eye, adult cotton rats by intracerebral and intranasal routes, on the conjunctiva and in the cornea, white rats inoculated intracerebrally and intranasally, rhesus monkeys inoculated intracerebrally, intranasally and subcutaneously, kittens inoculated intracerebrally, adult ferrets inoculated by the intracerebral, the intraperitoneal and the intranasal routes, and embryonated chicken eggs inoculated into the yolk, the allantoic and the amniotic sacs. However, tissue culture technics offer a large number of cell lines which support multiplication of adenoviruses and respond to infection with characteristic cytopathic changes. HeLa cells, epithelial-like cells derived by Gey from an epidermoid carcinoma of the cervix, have proved to be most generally useful for propagation of adenoviruses. In addition, these agents multiply and induce cytopathic changes in a variety of other epithelial-like cell lines derived from several types of cancer, human conjunctival membrane, nasal mucosa, bone marrow, tonsils, adenoids, liver and intestine, and maintained in continuous culture. Adenoviruses will also multiply in tissue cultures prepared from human tracheal epithelium, human amnion, monkey and rabbit kidney and rabbit tracheal epithelium. Undoubtedly, many other susceptible cells have been employed, or will be found to support multiplication of these agents. Although epithelial cells appear to be most susceptible to infection, fibroblasts in mixed cultures also are affected eventually. Whether adenoviruses propagate in these cells or damage the fibroblasts by a toxic action has not been determined.

The only animal shown to be readily susceptible to adenovirus infection is man. The Commission on Acute Respiratory Diseases (1947b, c) produced acute respiratory disease (ARD) by inhalation of a spray of filtered respiratory secretions from a characteristic case of acute respiratory disease (ARD). Subsequent studies indicated that the virus transmitted was identical with or immunologically closely related to type 4 virus (Ginsberg et al., 1955a). When inoculated intranasally into volunteers, type 1, 2, 3 or 4 adenovirus, previously passed in HeLa cells, resulted in the formation of neutralizing and complement-fixing antibodies but not in the production of clinical respiratory disease (Bell et al., 1956b; Southam et al., 1956). On the other hand, type 1 virus propagated in embryonic human kidney cells, when inoculated intranasally, produced pharyngitis in 2 of 4 volunteers who had no pre-existing neutralizing antibodies (Roden et al., 1956). When virus which had been grown in monkey kidney cells was rubbed on the conjunctiva, moderately severe catarrhal conjunctivitis and pharyngitis accompanied by systemic symptoms resulted (Bell et al., 1956b). Adenovirus type 4 or 7 injected intramuscularly by Hilleman et al. (1957b) induced fever, constitutional symptoms, and the production of antibodies, but multiplication of virus was not demonstrated. Type 8 virus, when instilled into the conjunctival sac after scraping of the conjunctiva or the cornea, resulted in follicular conjunctivitis, keratitis and corneal opacities characteristic of epidemic keratoconjunctivitis (Mitsui et al., 1957; Bietti and Bruna, 1957), and infection spread to susceptible contacts. However, instillation of type 8 virus without injury to the conjunctiva or the cornea did not initiate disease.

At least 5 serologic types are apparently of simian origin. Four of these types were obtained from monkeys, and one was isolated from the stool of a chimpanzee with a mild upper respiratory disease (Rowe et al., 1956b, 1958). It has not yet been determined whether disease can be initiated in monkeys or chimpanzees by inoculation of these types.

ETIOLOGY

The adenovirus group is composed of a number of viruses related by a common complement-fixing antigen and many similar biologic properties. Although the small antigenic particles detected by complement-fixation technics are immunologically similar but probably not identical for all viral types

FIG 105. FIG 105 Progressive alterations in nuclei of HeLa cells infected with type 1 adenovirus. A diagrammatic representation and a corresponding photograph of typical control and infected cells are shown (A) nuclear membrane, (B) nucleolus, (C) eosinophilic body, (D) basophilic core of eosinophilic inclusion; (E) rearranged chromatin; (F) basophilic granular cluster; (G) dense basophilic mass, and (H) glassy background. Cells were fixed in 95 per cent alcohol and stained with hemotoxylin and eosin (×800-900) (Adapted from Figs 1-10 *in* Boyer, G S, et al, 1957, Cytological and cytochemical studies of HeLa cells infected with adenoviruses, J Exper. Med *105*, 195-216)

plete within 15 to 30 minutes at room temperature (Ginsberg, 1956b) Cow, horse, or calf serum may neutralize adenoviruses in a manner similar to that of specific neutralizing antibodies (Gold and Ginsberg, 1957). This could be due to the presence of either nonspecific inhibitors or neutralizing antibodies in such animal sera No heat-labile inhibitor in human or animal sera is capable of inactivating adenoviruses

Adenoviruses, unlike a number of other viruses, do not cause hemagglutination of animal erythrocytes under the experimental conditions which have been tested However, when sheep or chicken red blood cells are treated with tannic acid, one or more adenovirus antigens adhere to the cell surface Such cells are then agglutinated by antiserum This test resembles the complement-fixation reaction and is not type-specific (Friedman and Bennett, 1957). The test can be made more nearly type-specific if antiserum is adsorbed with a pool of viruses other than the type for which antibodies are to be measured While viral particles will combine with tanned erythrocytes, the major antigen involved in this reaction is considerably smaller than the viral particle and is easily separated from it by high-speed centrifugation (Ross and Ginsberg, 1958)

Since the original isolation of adenoviruses from tonsils and adenoids and from army recruits with acute respiratory disease (ARD), the relationship of these agents to the etiology of disease has been a foremost problem It is apparent that the viruses can reside in cells of lymphoid tissue, probably for long periods, without causation of overt disease This phenomenon explains their isolation from tonsils, adenoids and mesenteric lymph nodes Whether the adenoviruses which can remain in the quiescent state, particularly types 1, 2, 5 and 6, ever produce recurrent disease is not clear Many strains of adenoviruses have been isolated from cases of clinical illness, and the patients from whom the viruses were isolated developed neutralizing and complement-fixing antibodies In particular, adenoviruses have been implicated etiologically in cases of nonbacterial pharyngitis, pharyngoconjunctival fever, conjunctivitis, ARD, viral or atypical pneumonia not associated with cold hemagglutinins or streptococcus MG agglutinins, and epidemic keratoconjunctivitis Specific types have been associated with certain of the diseases mentioned both in epidemics and in sporadic cases In these instances, the virus has been isolated from secretions of the organ involved, whether the throat, the eye, or the lung Adenovirus has been obtained frequently from stools of ill persons, although gastro-intestinal signs or symptoms are not a feature of any of the diseases with which the adenoviruses have been associated It is considered probable that the virus in pharyngeal secretions is swallowed, and because of its marked stability remains infectious until eliminated in the feces

DIAGNOSIS

The frequency of acute respiratory infections and the relative infrequency with which adenoviruses appear to cause these diseases suggest the difficulties which might be encountered in an attempt to make an etiologic diagnosis on clinical grounds During the course of an epidemic, particularly in recruits in the Armed Forces, it is relatively easy to diagnose either acute respiratory disease (ARD) or nonbacterial pharyngitis However, present evidence indicates that agents other than adenoviruses may also be the cause of nonbacterial pharyngitis and possibly acute respiratory disease (ARD) To some extent the type of virus implicated in a clinical illness may be suspected on clinical grounds Types 4 and 7 viruses are most frequently responsible for epidemics of acute respiratory disease (ARD), but occasional sporadic cases may be difficult to distinguish from infections due to type 3 virus The predominance of symptoms and signs referable to the pharynx in type 3 infections may be helpful in distinguishing nonbacterial pharyngitis from acute respiratory disease (ARD) With both nonbacterial pharyngitis and acute respiratory disease (ARD) constitutional symptoms are usually prominent, so that these symptoms do not assist in the differentiation from influenza and similar infections whose etiology is unknown. Nonbacterial pharyngitis and acute respiratory disease (ARD) must especially be distinguished from undifferentiated acute respiratory diseases of unknown etiology, streptococcal pharyngitis, herpan-

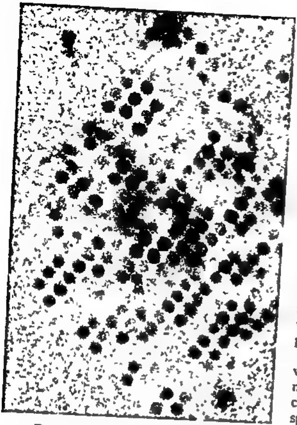

FIG 107 Thin section through an intranuclear crystal composed of type 4 adenovirus. Many of the particles exhibit well-defined internal structure Center-to-center spacing averages 65 mu (×80,000) (Morgan, C, et al., 1956, Structure and development of viruses observed in the electron microscope. IV. Viruses of the RI-APC group J Biophys. & Biochem Cytol. *2*, 351-360)

mains Electronmicroscopic examination of thin sections of types 3, 4 and 7 adenovirus-infected cells indicates that the crystal-like bodies are composed of viral-like particles as illustrated in Figure 107 (Morgan et al, 1956; Harford et al, 1956).

The mechanism by which adenoviruses induce their cytopathic effects is not known. However, these agents can damage susceptible cells in tissue cultures by a seemingly toxic effect in the absence of viral multiplication. Indeed, even virus made noninfectious by heating for 10 minutes at 56° C. can produce this cell damage ...

to the effect of viral infection (Boyer et al, 1957a).

Each adenovirus apparently contains at least 2 antigens which contribute to the immunologic properties and the identification of the agent. The group-specific antigen, by which the numerous types are classified collectively into a single family, is considered to be smaller than the viral particle per se and can be separated from the viral particle by high-speed centrifugation (Hilleman et al, 1955a) The group antigen is most readily detected and quantitated by complement-fixation technics. The reactivity of the viral particle itself in the complement-fixation system has not been determined. Pereira (1956) has shown some type-specificity by complement-fixation titrations using as antigenic material homogenized infected tissue cultures which must contain viral as well as smaller particles

The type-specific antigen is a portion of the viral particle and is readily identified and measured by neutralization technics in tissue culture. Antibody directed against the type-specific antigen neutralizes the infectivity of the homologous virus but does not prevent infection by heterologous types. Although the neutralization reaction does not follow multiple proportions, the relationship between the amount of antibody necessary to neutralize varying quantities of virus is linear on a logarithmic scale and has an exponential form (Ginsberg, 1956b). The slope of the neutralization line is approximately 2 0 for viral types 1, 2, 5 and 6 but is 1 0 for types 3, 4 and 7 viruses (Denny et al, 1958). The differences between types 1, 2, 5 and 6 on the one hand and types 3, 4 and 7 viruses on the other are emphasized again by these quantitative variations in the neutralization reaction (Table 26) Thus, with type 3, 4 or 7 virus a 10-fold change in the quantity of virus employed in the test results in a 10-fold inverse alteration of the neutralization titer obtained. A 10-fold increase in the amount of type 1, 2, 5 or 6 virus mixed with serum causes a 3-fold decrease in the neutralization titer measured. These data indicate the great importance of quantitative factors in neutralization ...

drugs Benefit has been reported from the local use of steroid compounds in epidemic keratoconjunctivitis, but the available data are still insufficient to evaluate this form of therapy It is perhaps not surprising that clinical trials of various specific agents, such as antibiotics, have not shown appreciable benefit to the patients, since Huebner et al (1954) have shown that the adenoviruses are resistant to these agents in the laboratory

EPIDEMIOLOGY

The occurrence of adenovirus infections is probably world-wide, although most of the data thus far available have come from studies in North America and Europe Man appears to be the principal reservoir for those types causing human disease Strains falling into the adenovirus group have been isolated from monkeys and chimpanzees

The importance of the adenoviruses in the total picture of respiratory disease seems at the present time to vary greatly with different population groups or units. In civilian populations, for example, surveys using the presence of complement-fixing and neutralizing antibodies as an index of prior infection indicate widespread infection of children, predominantly with types 1, 2, 5 and 6, and somewhat less extensively with type 3 (Huebner et al, 1954, Hilleman et al, 1955c, Jordan et al, 1956) Only rarely have antibodies for types 4 and 7 been found in children, data for the other types are not available A relatively high proportion of adults have antibodies, indicating previous infection with one or more types of adenoviruses In general, the proportion of persons showing specific antibodies for one or more types increases with age (Fig 108) It is not known how frequently infection with one of these viruses leading to the development of type-

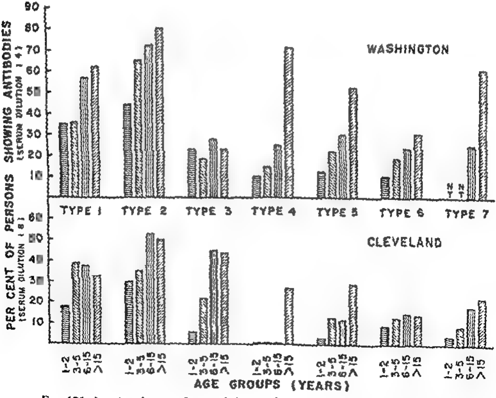

FIG 108 Age distribution of neutralizing antibodies to adenoviruses in Washington and Cleveland (Modified from Jordan, 1957)

gina, influenza, primary atypical pneumonia, psittacosis and Q fever.

Pharyngoconjunctival fever, characterized by the triad of clinical manifestations—fever, pharyngitis and conjunctivitis—occurs usually in epidemic form, is frequently associated with swimming and is caused by type 3 adenovirus in most proved instances, although in one epidemic type 7 virus was shown to be the responsible agent (Ormsby et al, 1957) This syndrome is readily recognized clinically, but again, agents other than adenoviruses also may be etiologically responsible.

Follicular conjunctivitis in epidemics or in sporadic cases has been shown to be due to various types of adenovirus, although type 3 virus has been implicated most frequently Numerous cases of nonbacterial conjunctivitis, including those seen in epidemics, appear to be caused by viruses other than adenoviruses For clinical diagnosis differentiation must be made from bacterial causes of conjunctivitis, inclusion conjunctivitis, Beal's acute follicular conjunctivitis, chronic follicular conjunctivitis (Oxenfeld type), Reiter's disease, conjunctivitis of the erythema multiforme syndrome, and conjunctivitis due to Newcastle disease virus. In addition, differentiation from infections associated with corneal and uveal involvement must be made

Diagnosis of epidemic keratoconjunctivitis is now becoming clearer and differentiation from other forms of keratitis more easily accomplished since the identification of the probable etiologic agent Present evidence indicates that most, if not all, cases of epidemic keratoconjunctivitis are caused by an adenovirus. More specifically, type 8 virus appears to be the cause of the majority of cases, although in some epidemics type 3 or type 7 adenovirus may be the responsible agent The characteristic features, which consist of constitutional manifestations, inflammation of the conjunctiva with edema of the lids, regional lymphadenopathy and superficial corneal opacities, strongly suggest the diagnosis on clinical grounds Epidemiologic characteristics of the disease frequently assist in diagnosis of the infection Differential diagnosis should include trachoma, pemphigus and keratoconjunctivitis or keratitis due to viruses causing such diseases as herpes simplex, lymphogranuloma venereum, variola, vaccinia, measles, mumps, herpes zoster, varicella, molluscum contagiosum and common warts

Laboratory confirmation is required in most cases to establish a definite etiologic diagnosis. The virus can be isolated from pharyngeal, lower respiratory or ocular secretions, or from stools. Secretions from the pharynx or the eye can be obtained by swabbing the organ or washing with broth or balanced salt solution The virus is isolated by inoculating the infected material into a tissue culture of susceptible cells such as HeLa, KB, or human amnion cells. The presence of virus is recognized by the characteristic cytopathic changes which occur in the cells from 2 to 21 days later, depending upon the quantity of virus present in the material obtained from the patient Then the virus can be identified as an adenovirus by the complement-fixation reaction. To determine the type of the virus, neutralization titrations must be done with type-specific sera from immunized rabbits, hamsters or guinea pigs

A serologic diagnosis of adenovirus infection can be accomplished with a serum obtained during the acute stage of the illness (first 5 days), and a second serum procured no less than 14 and preferably 21 days after onset of the disease Complement-fixation titrations with the paired sera and any type of adenovirus as antigen will show an increase in titer of antibody in the second serum specimen To determine the specific virus type which caused the infection, neutralization titrations must be done with the common types of adenoviruses known to cause infection The hemagglutination reaction can be employed for serologic diagnosis but does not appear to offer any advantages over complement-fixation titrations.

TREATMENT

Symptomatic and supportive care, as in other infectious diseases, is the basis of treatment The sulfonamide drugs, penicillin and the so-called broad-spectrum antibiotics have no apparent effect on the course of illness Convalescent serum, gamma globulin and virus vaccine have no value in therapy. Bacterial complications are so rare that there is no need for the prophylactic use of antibiotic

Commission on Acute Respiratory Diseases (1947b, c) which showed that volunteers inoculated with throat washings from a case of acute respiratory disease (ARD) were subsequently immune to reinoculation with the same material

The relationship of adenoviruses to acute respiratory disease (ARD) of recruits was first demonstrated by Hilleman and Werner (1954) who isolated type 4 virus from cases occurring during an epidemic among the troops at Ft Leonard Wood, Mo The particular epidemic was made up of cases of both influenza A and acute respiratory disease (ARD), but after isolation of the viruses the two diseases could be distinguished by appropriate serologic studies (Hilleman et al, 1955b) Subsequent investigations have shown that most cases in outbreaks of acute respiratory disease (ARD) are due to types 4 and 7 viruses, although a few cases may be due to type 3, and one outbreak due to type 14 has been reported (Hilleman et al, 1955d, 1957a, Berge et al, 1955, Dingle, 1955, Woolridge et al, 1956, Rowe et al, 1956a, van der Veen and Kok, 1957) Infection is apparently widespread during the period of the epidemic, since as many as 80 per cent of the recruits have been shown to acquire serologic evidence of infection during an 8-week period encompassing the epidemic Some 20 to 40 per cent of the recruits may require hospitalization, and another 20 per cent may require dispensary care The remainder of the infections are apparently subclinical Duration of infectivity in the individual patient is apparently short, since Rowe et al (1956a) found that virus could be isolated from 88 per cent of patients on the first day of illness and 75 per cent on the second to the fourth day, but that it could not be detected thereafter Duration of specific immunity has not yet been adequately determined, although Hilleman et al (1955d) have demonstrated the persistence of complement-fixing and neutralizing antibodies for 1 year or more, and Jordan et al (1956) have shown the persistence of neutralizing antibodies to type 4 for at least 8 years in civilian adults Katz et al (1957) have also demonstrated the persistence of specific antibodies for periods of at least a year after infection

With the exception of 2 outbreaks of illness due to type 7 virus, 1 in England and 1 in Canada (Tyrrell et al, 1956, Ormsby et al, 1957), outbreaks due to types 4 and 7 have not been reported in civilian populations In fact, only 3 strains of type 4 virus have been isolated from civilian groups Moreover, antibody studies suggest that illnesses due to types 4 and 7 have been extremely rare both in Washington and Cleveland (Fig 108) These findings may explain the epidemic occurrence of acute respiratory disease (ARD) in recruits, since few of them at the time of induction into the services have antibodies to the predominant types, namely, 4 and 7, which cause the disease. Presumably, then, a highly susceptible population is brought together in the barracks of the training camp under conditions favorable to the spread of the virus The mode of spread is undefined but is considered to be via the respiratory tract and to some extent at least may depend upon intimacy of contact

Pharyngitis or Pharyngoconjunctival Fever

Adenovirus infections causing pharyngitis or pharyngoconjunctival fever occur sporadically in both military and civilian populations The epidemic occurrence of this form of adenovirus infection in civilians is found chiefly in children during the summer months (Parrott et al, 1954, Bell et al, 1955, Ginsberg et al, 1955b, Ormsby et al, 1957) The outbreaks are due principally to type 3, two outbreaks due to type 7 have been reported Sporadic cases are most frequently due to type 3, less often to types 2 and 5, and rarely to other types In familial or institutional outbreaks, the virus usually can be isolated only from patients who also show an increase in titers of antibody in their convalescent sera The agent has not been found in well persons regardless of intimacy of contact There appears to be a good correlation between the presence of specific neutralizing antibody and resistance to infection

The attack rate is variable in different outbreaks but may be as high as 70 per cent over a few weeks' time in children in camp (Bell et al, 1955) The incubation period is estimated to be 6 days and the period of communicability to cover a period of an additional 10 days, as indicated by isolation of virus from the pharynx In outbreaks in families the infectiousness is indicated by a secondary attack rate of about 50 per cent in children aged <1 through 9 years, with the rate decreasing with increasing age No sex difference is found in children through 9 years of age, but in the older age groups males appear to be attacked less frequently than fe-

Modified from Jordan (1958)

specific antibodies is associated with symptoms of respiratory disease Attempts to isolate the agents from patients with respiratory disease in civilian groups, such as hospitalized patients, students, nurses, families, etc, suggest that these viruses cause a very small proportion of the cases of respiratory disease The frequency of isolation of all types has varied from less than 1 per cent to approximately 2 per cent of all respiratory illnesses in various series Complement-fixation and neutralizing antibody studies in the same group of patients indicate that at the most only 4 to 5 per cent of the respiratory illnesses are due to adenoviruses (Table 27).

In addition to sporadic occurrence, however, epidemics of adenovirus infections occur in military recruits and in civilian populations, especially in children, so that further discussion of the epidemiology of the adenovirus group will consider acute respiratory disease (ARD), nonbacterial pharyngitis and epidemic keratoconjunctivitis separately.

ACUTE RESPIRATORY DISEASE (ARD)

The occurrence of epidemics of acute respiratory disease (ARD) or febrile catarrh in [illegible]

beginning 2 or 3 weeks after the arrival of the men on the post and running its course in the subsequent 3 to 4 weeks In this respect its behavior is similar to that of influenza Epidemics occur particularly during the winter months During this season the attack rate may be high, and from 20 to 40 per cent of the recruits may be sufficiently ill to require hospitalization In training posts where there is a continuous induction of recruits at weekly or monthly intervals, each unit in succession will experience the epidemic wave with remarkable consistency During summer months the epidemic occurrence of the disease may disappear entirely, but those units arriving at the post during the summer may undergo an epidemic wave in the fall even after several weeks of training. Men who comprise the cadre responsible for training the recruits and have had months or years of prior military experience seldom are involved in these outbreaks The epidemic wave in each organizational unit appears to confer group immunity—a process known as seasoning—since this unit will not again undergo an epidemic of acute respiratory disease (ARD). In this respect the disease differs from influenza, since outbreaks of influenza involve both recruits and seasoned men Thus the epidemiologic behavior suggests that there is a high degree of susceptibility among recruits, that the outbreaks are caused by a single agent or by closely related agents and that the disease is followed by relatively solid immunity. The latter observation was confirmed by the volunteer studies of the

Commission on Acute Respiratory Diseases (1947b, c) which showed that volunteers inoculated with throat washings from a case of acute respiratory disease (ARD) were subsequently immune to reinoculation with the same material

The relationship of adenoviruses to acute respiratory disease (ARD) of recruits was first demonstrated by Hilleman and Werner (1954) who isolated type 4 virus from cases occurring during an epidemic among the troops at Ft Leonard Wood, Mo The particular epidemic was made up of cases of both influenza A and acute respiratory disease (ARD), but after isolation of the viruses the two diseases could be distinguished by appropriate serologic studies (Hilleman et al, 1955b) Subsequent investigations have shown that most cases in outbreaks of acute respiratory disease (ARD) are due to types 4 and 7 viruses, although a few cases may be due to type 3, and one outbreak due to type 14 has been reported (Hilleman et al, 1955d, 1957a, Berge et al, 1955, Dingle, 1955, Woolridge et al, 1956, Rowe et al, 1956a, van der Veen and Kok, 1957) Infection is apparently widespread during the period of the epidemic, since as many as 80 per cent of the recruits have been shown to acquire serologic evidence of infection during an 8-week period encompassing the epidemic Some 20 to 40 per cent of the recruits may require hospitalization, and another 20 per cent may require dispensary care The remainder of the infections are apparently subclinical Duration of infectivity in the individual patient is apparently short, since Rowe et al. (1956a) found that virus could be isolated from 88 per cent of patients on the first day of illness and 75 per cent on the second to the fourth day, but that it could not be detected thereafter Duration of specific immunity has not yet been adequately determined, although Hilleman et al (1955d) have demonstrated the persistence of complement-fixing and neutralizing antibodies for 1 year or more, and Jordan et al (1956) have shown the persistence of neutralizing antibodies to type 4 for at least 8 years in civilian adults Katz et al (1957) have also demonstrated the persistence of specific antibodies for periods of at least a year after infection

With the exception of 2 outbreaks of illness due to type 7 virus, 1 in England and 1 in Canada (Tyrrell et al, 1956, Ormsby et al, 1957), outbreaks due to types 4 and 7 have not been reported in civilian populations In fact, only 3 strains of type 4 virus have been isolated from civilian groups Moreover, antibody studies suggest that illnesses due to types 4 and 7 have been extremely rare both in Washington and Cleveland (Fig 108) These findings may explain the epidemic occurrence of acute respiratory disease (ARD) in recruits, since few of them at the time of induction into the services have antibodies to the predominant types, namely, 4 and 7, which cause the disease. Presumably, then, a highly susceptible population is brought together in the barracks of the training camp under conditions favorable to the spread of the virus The mode of spread is undefined but is considered to be via the respiratory tract and to some extent at least may depend upon intimacy of contact

Pharyngitis or Pharyngoconjunctival Fever

Adenovirus infections causing pharyngitis or pharyngoconjunctival fever occur sporadically in both military and civilian populations The epidemic occurrence of this form of adenovirus infection in civilians is found chiefly in children during the summer months (Parrott et al, 1954, Bell et al, 1955, Ginsberg et al, 1955b, Ormsby et al, 1957) The outbreaks are due principally to type 3, two outbreaks due to type 7 have been reported Sporadic cases are most frequently due to type 3, less often to types 2 and 5, and rarely to other types In familial or institutional outbreaks, the virus usually can be isolated only from patients who also show an increase in titers of antibody in their convalescent sera The agent has not been found in well persons regardless of intimacy of contact There appears to be a good correlation between the presence of specific neutralizing antibody and resistance to infection

The attack rate is variable in different outbreaks but may be as high as 70 per cent over a few weeks' time in children in camp (Bell et al, 1955) The incubation period is estimated to be 6 days and the period of communicability to cover a period of an additional 10 days, as indicated by isolation of virus from the pharynx In outbreaks in families the infectiousness is indicated by a secondary attack rate of about 50 per cent in children aged <1 through 9 years, with the rate decreasing with increasing age No sex difference is found in children through 9 years of age, but in the older age groups males appear to be attacked less frequently than fe-

males, the difference being in the order of 1.2 in Bell's studies

The mode of spread is generally considered to be person-to-person via the respiratory tract, but the virus has been isolated from stools, and there is some indication that certain outbreaks have been related to swimming pools (Bell et al, 1955; Ormsby and Aitchison, 1955, Cockburn et al., 1956). This observation has led to the hypothesis that the eye might be the portal of entry of infection Some support for this concept is obtained from the volunteer studies of Bell et al. (1956b) who were able to induce conjunctivitis with or without nasopharyngitis by rubbing the virus on the palpebral conjunctiva with a swab but obtained no illnesses, or only minor illnesses, when the virus was inoculated intranasally In contrast with these results, however, Roden et al (1956) were able to transmit infections to volunteers by the intranasal inoculation of type 1 adenovirus.

The epidemiologic significance of the isolation of various types of adenoviruses from tonsillar and adenoidal tissue removed surgically has not yet been determined It is possible that these viruses lead a symbiotic or latent existence in lymphoidal tissue and that with the proper stimulus they may excite recurrent infection in the person harboring them, or they may spread to initiate other cases or an epidemic In a few instances the same strain of virus has been isolated from the pharynx of an individual at times of recurrent respiratory infections Whether or not the same virus was the cause of these infections has not been determined

The relationship between the properties of the virus in laboratory cultures and the epidemiologic behavior is not clear In some situations (Dingle et al, 1955), for example, the type 3 virus does not seem to spread widely in the population during an epidemic period In general, the virus can be recovered only from persons who were ill, those who remained well give no serologic evidence of infection. Subclinical infection, which occurs readily with many viral diseases, such as poliomyelitis, thus does not seem to be common for the type 3 virus This observation has led to the postulate that the epidemiologic behavior of the virus may be related in part to the fact that it is neither adsorbed well to tissue cells nor easily released However, the epidemiologic behavior of acute respiratory disease (ARD) due to types 4 and 7 adenoviruses is in marked contrast, as indicated in the preceding section, since in these outbreaks the viruses appear to spread widely and rapidly and the rate of subclinical infection is high, as shown by serologic studies Yet the behavior of these types in the laboratory with respect to adsorption to and release from cells in tissue culture is comparable with that of other types.

Conjunctivitis and Keratoconjunctivitis

There is insufficient information to describe the epidemiologic behavior of follicular conjunctivitis occurring apart from associated infections of the respiratory tract. Presumably, however, its behavior would be similar to that of pharyngitis and pharyngoconjunctival fever described above. The volunteer studies of Bell et al (1956b) have demonstrated that resistance and susceptibility to infection induced by swabbing the virus onto the conjunctiva can be correlated with the presence or the absence, respectively, of specific antibody in the sera.

Sporadic cases of keratoconjunctivitis occur not infrequently and in some instances have been associated with types 3, 7 and 8 adenoviruses by isolation of the virus from scrapings of the conjunctiva and by the demonstration of increases in antibody titers to the virus in convalescent sera However, the epidemic occurrence of the disease is more striking, and large outbreaks have occurred in the Far East, in Hawaii, in the United

toconjunctivitis show a significant increase in neutralizing antibodies to adenovirus type 8 during the acute phase of the disease and a gradual loss of titer thereafter Moreover, the sera from patients with epidemic keratoconjunctivitis in Japan, Italy, Switzerland and North America have been shown to contain neutralizing antibodies to this virus, whereas such antibodies were absent in the general population in these areas Thus the present evidence suggests that adenovirus type 8 is involved in the production of the disease, but further data are needed to establish a firm etiologic relationship The mode of spread of epidemic keratoconjunctivitis is not known, although trauma to the conjunctiva from dust and dirt in offices and dispensaries where

proper aseptic technics are not employed may be a factor in its distribution

CONTROL MEASURES

The general measures that have been employed in an attempt to control the spread of adenovirus infections are similar to those that have been employed for other diseases presumably spread via the respiratory tract. The principal studies have been carried out in military populations composed of recruits and have consisted of such procedures as the oiling of floors and blankets, the use of double bunks to increase the space between beds, ultraviolet lights and the use of aerosols. These various procedures have had either little or no effect, or at best have resulted in a reduction of only approximately 5 per cent. In general, isolation procedures for patients have little or no effect. Chlorination of swimming pools is advisable, should it prove that adenovirus infections may be spread from such a source, since Clarke et al (1956) have shown that these agents are sensitive to the action of chlorine.

With respect to epidemic keratoconjunctivitis, rigid asepsis in the medical divisions of factories and plants should be employed to prevent the spread of infection by hands of attendants or by instruments. Isolation of patients with the disease has also been advised.

The use of specific preventive measures such as gamma globulin or adenovirus vaccines is indicated under special circumstances in which attack rates can be predicted to be high, such as at military recruit training centers. That a vaccine, when obtained, would be effective for the prevention of acute respiratory disease (ARD) of recruits was suggested by the epidemiologic behavior of the disease, which indicated the development of a relatively permanent immunity in a population that had experienced an epidemic, and by the demonstration of immunity in the individual person by challenge inoculation in volunteer studies. In addition, (1) susceptibility or resistance to clinical infection was correlated directly with the absence or the presence, respectively, of circulating neutralizing antibodies for type 4 virus, (2) such antibodies developed during convalescence (Ginsberg et al, 1955a), and (3) the adenoviruses appear to be good antigens. On theoretical grounds, therefore, it could be predicted that active immunization and possibly passive immunization would be effective for the prevention of ARD in recruits (Dingle, 1955). The studies of Huebner et al (1955), Bell et al (1956a), Hilleman et al (1956, 1957c, d) and Stallones et al (1957) have demonstrated that a satisfactory vaccine can be prepared containing 2 or 3 types of adenoviruses (types 3, 4 and 7). The vaccines are antigenic, and 1 dose apparently gives almost maximum antibody response. Their use in several studies has demonstrated a reduction of from 85 to 95 per cent in the attack rate of adenovirus infections in immunized groups in comparison with control groups not receiving such vaccine.

There is little reason to doubt that adenovirus vaccines can produce antibodies in children and that resistance to infection would follow their use in civilian populations. At the present time the low incidence of adenovirus infections in the civilian population, as already pointed out, would raise serious question as to the advisability of the widespread use of an adenovirus vaccine except for special situations, such as in orphanages, where a high incidence of infection might be predicted. In fact, Jordan (1958) has estimated, on the basis of data on incidence of adenovirus infections in civilian populations, that the use of a vaccine which completely prevented infection would result in only a 6 per cent reduction in the number of common respiratory illnesses experienced by an average child during the first 10 years of life. Similarly, the low incidence of infection in other civilian groups, such as university student populations, does not warrant immunization with adenovirus vaccine at the present time.

No data are yet available regarding the possible efficacy of a type 8 adenovirus vaccine for the prevention of epidemic keratoconjunctivitis. However, the relatively rapid fall of specific antibodies in the sera of patients convalescent from the disease suggests the possibility that any immunity conferred by such a vaccine might be of relatively short duration and that repeated inoculations of the vaccine might be necessary to provide effective protection.

Influenza

(SYNONYMS *La grippe*, grip, febrile catarrh, catarrhal fever, acute nasopharyngitis, epidemic catarrh, epidemic influenza)

INTRODUCTION

Influenza is an acute infectious respiratory disease of man, commonly encountered in epidemic form, caused by one of the influenza viruses Clinically, there is sudden onset with fever, myalgias, pharyngitis, cough, leukopenia, the course is usually self-limiting in 3 to 4 days Constitutional manifestations ordinarily overshadow respiratory features Complication of bronchitis and bronchopneumonia are frequent Epidemics are characterized by rapid dissemination high morbidity and low mortality, however, they may be *world-wide and of such severity as to attain* catastrophic proportions Four distinct immunologic types of influenza virus A, B, C and D, have been recognized and classified according to the plan of Horsfall et al (1940) Influenza A and influenza B have been encountered most frequently and therefore are the best studied

HISTORY

What is now called influenza is readily recognized in dramatic descriptions covering many centuries of epidemics arising explosively in a population, spreading rapidly and widely over large areas The comment is made repeatedly that many sickened but few died of it except the old and the infirm The clinical manifestations, too, are in keeping with modern observations Short wrote of the epidemic of 1557—"it began with a roughness of the jaws, small cough, then a strong fever, with a pain of the head, back and legs, some felt as though they were over the breast and had a weight at the stomach, all which continued to the third day at the farthest, there the fever went off with a sweat or bleeding at the nose In some few, it turned to pleurisy, or fatal peri pneumony" (Thompson 1852)

From 1510 to 1930 some 30 of the prevalences were clearly considered pandemic, and numerous outbreaks of lesser extent were described For example, between 1800 and 1875 Hirsch (1883) records 55 years in which he states influenza was epidemic in various parts of the world But obviously the more pronounced occurrences have been best described The outbreak of 1743 was considered a virulent pandemic, and Jordan (1927) states that the actual number of deaths occurring in London during the height of the epidemic was as great in proportion to the population as it was in American cities in 1918 *It was in this epidemic that the name* "influenza" was derived from the Italian phrase attributing the origins of the disease to *un influenza di freddo* That of 1782 was called a great pandemic in Asia and Europe with apparently a high frequence of complications At this time there was strong support for the thesis that the disease was infectious and contagious with a specific cause rather than the result of meteorologic or telluric influences However, it was not until the

pandemic period of 1889-92 that relatively accurate data were compiled and bacteriologic studies undertook to seek a specific etiologic agent. Pfeiffer (1892) then described *H. influenzae* and assigned to it primary causative significance And in 1889-90 Abbott demonstrated the independence of direction of spread from that of prevailing winds The entire history of influenza was climaxed by the greatest of all the pandemics in 1918-19 which, it is estimated, resulted in the death of some 20 million persons The extensive observations of that episode and efforts to explain it have since been a dominant concern of students of respiratory disease and epidemiology They have been reviewed exhaustively by Thomson and Thomson (1933, 1934)

Despite the variations, major outbreaks retain close similarity in their apparently abrupt development in an area, their wide dispersion, the mild 3-day nature of the majority of illnesses, the relatively low case fatality, and the tendency to subside rapidly and be followed by lesser waves over the next several years. These trailers have been considered part of the pandemic phenomenon

Modern knowledge of the causal agents of human influenza begins with isolation in ferrets of a virus from cases of influenza by Smith, Andrewes and Laidlaw (1933) who also noted that convalescent sera of the patients contained neutralizing antibodies to the virus The isolation of virus was promptly confirmed in America (Francis, 1934), and it was demonstrated that the specific antibodies actually develop during the disease. Virus was adapted to mice, serologic tests were developed, and opportunity to study the nature and the distribution of the virus was thus provided It was also shown that the virus induced in human volunteers a disease clinically characteristic of influenza This virus is now called Type A, and the disease influenza A has been followed in repeated outbreaks, especially 1936-37, 1943, 1947-49, 1957.

Studies at this time demonstrated that the virus of swine influenza (Shope, 1931) was antigenically related to, but not identical with, influenza A virus from man It was shown (Magill and Francis, 1936, 1938; Francis and Magill, 1938; Smith and Andrewes, 1938) that antigenic differences were demonstrable between strains of Type A, and the subject of antigenic variation among strains of influenza virus has become a problem of great theoretical and practical concern.

In 1940 a second etiologic type, Type B influenza virus, was identified with the epidemic current at that time as well as with earlier prevalences (Francis, 1940, Magill, 1940). It, too, has since been recognized in widespread outbreaks.

A virus isolated from a patient in 1949 (Taylor) was found to be distinct from Types A and B viruses, and the antibody response of the patient was specific for the new virus In 1950 another strain was isolated and shown to be associated with an institutional outbreak of influenza This virus has been designated Type C influenza virus (Francis et al., 1950). Later, several small outbreaks have been identified in various countries, but wide distribution of the infection is shown by the high frequency of antibody in the general population

More recently a virus isolated in Japan from newborn pneumonitis (Sendai virus, hemagglutinating virus of Japan) (Kuroya et al, 1953) was shown by serologic studies to be prevalent in the United States; on this basis and the similarity in characteristics of that virus to other influenza viruses it was tentatively designated Type D (Jensen et al, 1955, Francis, 1955) Scattered cases have been detected, and in 1956 a large outbreak of influenza in Vladivostok was reported from which virus of this type was isolated, and serologic studies indicated its etiologic relationship (Gerngross 1957, Gorbunova et al, 1957)

Variations of strains within the type have been observed in different years The 2 most distinct variants of Type A influenza virus recovered from man have been those of 1946-47 (designated A-prime by the Commission on Influenza) and the Asian strains of 1957 Each has been associated with widespread outbreaks. Modifications of Type B strains have also appeared with those of 1945, 1952 and 1954-55 quite different antigenically from earlier strains. In view of the multiple types and subtypes and their comparative independence of distribution, interpretation of waves and recurrences noted in earlier descriptions of pandemic prevalences is at present uncertain.

CLINICAL PICTURE

The symptoms of uncomplicated influenza are disturbing to no one but the patient unless they affect a sufficient number of persons

to interrupt the functions of the group or the community

The incubation period of influenza is ordinarily 1 to 2 days Experimental infection by direct inhalation of fine sprays of virus has at times exhibited even shorter incubation periods The onset of illness is abrupt with sudden chilliness or distinct chill, fatigue, headache and general achiness The temperature rises rapidly in 12 to 24 hours to *a level of 101° to 104° F* *Diffuse headache* and severe muscular aching of the back and the extremities are usual in adults but are generally less marked in children The patient experiences a sense of fatigue or weakness building rapidly to prostration Ocular tenderness, conjunctival injection and watery eyes are common, usually without photophobia *Although nasal or nasopharyngeal* irritation may be noted early, constitutional symptoms are more prominent than evidence of respiratory infection Coryza is rarely prominent, but sneezing and mild discharge are not uncommon Epistaxis, probably from viral injury to nasal epithelium, occurs in a variable manner Truly sore throat is uncommon *In the next 24 hours the fever reaches* a sustained level The nose may be obstructed The throat feels dry and full Laryngitis with hoarseness and a hacking, unproductive cough is frequent, substernal soreness may be noted These manifestations probably reflect the effect of the virus on the lower respiratory mucosa There is little appetite, but nausea, vomiting and diarrhea are not common features At the height of the uncomplicated disease physical findings are few The patient is apathetic *The face is flushed, and the* conjunctivae are suffused The nasal mucous membranes are frequently bright red, and areas of *hemorrhage may be noted* *The* tongue is moderately coated The nasopharynx, the oropharynx and the soft palate are red and glazed with a shiny mucoid coating The lymphoid follicles, particularly those on the soft palate, are usually enlarged and dewy in appearance Purulent exudate is not seen on the tonsils or the pharyngeal wall Muscular soreness, *occasionally* hyperesthesia, may be detected In perhaps a third of the patients scattered sibilant mucous rales *may be heard over the larger bronchi*, but evidence of pulmonary involvement is otherwise absent The heart rate is variable, slight tachycardia is common; or a relative *bradycardia may be noted* *Blood pressure may be* somewhat lower than normal The abdomen is usually negative Splenomegaly is not ordinarily encountered Signs of encephalitic disturbance are reported but uncommon except as they reflect febrile reactions The leukocyte count ranges from 6,000 to 8,000, but in about one third of cases leukopenia occurs *A relative increase of lymphocytes is noted* Leukocytosis can be considered as evidence of complications Urinary findings are ordinarily limited to some febrile albuminuria Bacteriologic blood cultures are negative Bacteriologic examination of the throat has revealed no consistent bacterial accompaniment of influenza virus infection, however, the presence of *significant pathogens* in the cultures should be considered an additional risk to the patient In the ordinary case roentgenograms of the chest show little, some increases in hilar shadows may be noted

There may be some fluctuation in temperature, but 3 to 4 days after onset it falls sharply or declines to a normal range A slight afternoon rise may be noted for another day or two Even in severe outbreaks the great bulk of cases behave as mild "3-day fevers" Convalescence ordinarily proceeds rapidly, but annoying cough often persists for some time Despite the apparent recovery, distressing features of the disease may appear when the patient undertakes full activity too soon Fatigue and weariness are often troublesome, this is less pronounced in children and young adults with their greater reserves *In older persons it may be a prolonged course* Mental depression and difficulty in concentration may be marked The patient may experience palpitation, especially on exertion, rapid pulse or bradycardia may continue The nature of this disturbance is not known but it, too, suggests a form of "toxic" injury like that of the constitutional reaction

Pulmonary complications are the most common They are to be suspected if temperature and *symptoms persist beyond* the 4th or the 5th day There may be tracheitis, with increased substernal tightness or pain and painful cough with thick, tenacious sputum Dyspnea and cyanosis may develop Bronchitis,

bronchiolitis or pneumonia may supervene. Since these conditions are commonly associated with bacterial infection, the pulmonary signs are influenced by the nature of the bacterium as are the x-ray findings. In other instances, the temperature and the symptoms may have subsided, and the patient has begun to move about when a chill and sudden rise of temperature occur with a rapid return of symptoms Frequently, these episodes have been referred to improperly as relapses, as if of the primary illness, but they, too, usually represent the onset of bacterial pulmonary complications Leukocytosis develops, blood cultures may be positive, and examination of the sputum provides information of the complicating organism. The course will depend on the severity and the nature of the bacterial agent and the response to therapy Diffuse bronchopneumonia, lobar pneumonia, empyema or pneumothorax may occur. In a small proportion of cases a fulminant pneumonia ensues. The patient may appear to have a characteristically mild illness for 1 or 2 days when, acutely, extreme dyspnea and prostration develop Within a matter of hours the patient is dangerously ill and presents a shocked appearance with livid or heliotrope cyanosis, sweating, tachycardia, feeble pulse and low blood pressure Temperature may fall below normal Cough is feeble, and a thin serosanguinous fluid may exude from the respiratory tract Instances have been noted in which fluid really ran from the lung when the head was placed in a dependent position The physical signs in the chest may be very misleading Diffuse rales, more prominent at the bases, are heard, breath sounds are irregularly suppressed or perhaps exaggerated. The picture is really that of inflammatory pulmonary edema Roentgenograms may reveal patchy opacities or a diffuse haziness in the lower lung fields The most common organism associated with the virus infection in these cases has been a coagulase positive staphylococcus pyogenes Although acute staphylococcal infection of itself may produce a severe pneumonitis with diffuse involvement, in the presence of viral injury an additive effect occurs. Rapid deaths of somewhat similar clinical course also occur when other organisms are encountered. In some instances no bacterial component has been identified, and in epidemics associated with virulent strains of virus it seems likely that virus alone may cause these severe illnesses as in experimental animals. Persons with mitral stenosis appear to be especially vulnerable as if the development of alveolar fluid increased the probability of decompensation and further exaggeration of the pulmonary difficulty. Patients with other forms of advanced heart disease or chronic pulmonary fibrosis may tolerate the disease poorly.

Significant pneumonic complications among cases from the general population in usual epidemics scarcely exceed 1 per cent of the total. They are more frequent in young children and people over 50 years of age. In the epidemic of 1889-90 the incidence of pneumonia among cases of influenza was estimated to be 5 per cent. But in the severe pandemic of 1918 it was still higher, and in certain military installations an incidence of 20 to 30 per cent of pneumonia was noted with a case fatality in some as high as 30 per cent (Jordan 1927, Hall, 1928) Moreover, in 1918 an excessively high frequency was noted in persons of 20 to 40 years of age, particularly among males Obviously, the increased incidence of influenza results in an increased frequency of pneumonia at all times.

Influenza acquired during pregnancy often results in miscarriage or abortion It seems probable that congenital defects are also increased. There is an increased maternal and infant mortality so that influenza is a serious complication of pregnancy.

The clinical picture is essentially the same for influenza A and influenza B. The characteristics of influenza C are less clearly mapped, but on the basis of identified cases the presenting features are fever, headache, and coryza, which is more prominently mentioned than with other types (Francis et al, 1950; Taylor, 1951). On the other hand, the tendency of influenza C cases to be found in the midst of other identifiable influenza prevalences indicates the relative similarity in symptomatology to mild influenza. There are suggestions from volunteer studies that the incubation period may be as long as 5 to 7 days, although its development in the egg is similar in time to other strains (Quilligan et al, 1954).

The HVJ or Sendai virus infection, which

now called influenza D, was first described as a form of severe pneumonitis in newborn infants (Sano et al, 1953) The prominent symptoms and signs were high fever, respiratory distress, cyanosis, rhinopharyngitis, leukocytosis; diffuse shadows were seen on roentgenograms. On the basis of volunteer experiments, an incubation period of about 48 hours was followed by sharp febrile response for 2 days, pulmonary shadows and a second febrile reaction about the 10th day (Kuroya et al, 1953) Of 9 sporadic infections noted in Scotland, 3 had pneumonia, the others were considered as influenza (Grist et al, 1957) In the Vladivostok epidemic among adults influenzalike illness occurred with fever commonly as long as 6 days, pulmonary involvement was seen as a complication without recorded fatalities (Gerngross, 1957)

PATHOLOGIC PICTURE

Most of the information as to the pathologic changes occurring in influenza of man is derived from fatal pneumonia cases in which bacterial invaders play a prominent role As a result, a great complexity of pictures is described from which the viral injury must be extrapolated However, studies in experimental animals with influenza viruses have resulted in a clear picture of the primary viral injury Influenza virus exerts a selective injury on the ciliated respiratory epithelium Within 48 hours after infection of a ferret with a well-adapted strain, the nasal respiratory epithelium is largely destroyed, leaving only the germinative basement membrane The adjoining olfactory and squamous epithelia are essentially unaffected (Francis and Stuart-Harris, 1938) Regeneration begins rapidly from the basement layer, and by the 6th day a transitional type of epithelium composed of polyhedral cells 3 to 4 layers deep is rather uniformly present Repair proceeds in the next week through stages of stratified squamous, hyperplastic columnar and the return of relatively normal ciliated columnar cells excreting mucus However, islands of cells which have not completely differentiated may still remain Studies of the lower respiratory tract have shown in ferrets (Francis, 1934, Shope, 1934, Brightman, 1936), swine (Shope, 1936), and mice (Straub, 1937) that the earliest lesion is the necrotizing damage to the respiratory ciliated epithelium The earliest injury may be more consistent in the bronchioles than in the trachea and the primary bronchi (Stuart-Harris, 1953). The epithelium of the terminal respiratory bronchioles is made up of cuboidal nonciliated cells which do not secrete mucus, this tissue is not generally destroyed The severity of epithelial injury is undoubtedly influenced by the virulence of the strain

In ferrets and mice extensive pulmonary involvement develops about the hilum and extends peripherally, involving primarily the dependent lobes Entire lobes or even most of the lung may be affected The pleura is smooth, glistening and taut Grossly, the affected portions of the lung are distended and firm, purplish in color and filled with edema fluid Large amounts of serous fluid exude from the cut surface and from the bronchi after which the tissue becomes wrinkled and rubbery

Microscopically, in addition to irregular epithelial necrosis, the alveolar walls are swollen, and the spaces are distended with edema fluid and hemorrhagic extravasations The cellular exudate is a scanty distribution of large pale-staining mononuclear cells There are hyperemia and edema of the bronchial and bronchiolar tunica Peribronchiolar collections of round cells are seen Necrotic exudate is present in the lumen There is dilatation of the blood vessels, edema of their walls and some perivascular cuffing The character of the pulmonary lesion is that of a profuse edema secondary to the epithelial injury rather than an acute inflammatory pyogenic pneumonitis With recovery, epithelial hyperplasia and regeneration proceed more slowly than in the turbinates Nodular hyperplastic overgrowths are prominent These pneumonias are bacteria-free and are clearly related to virus alone Shope's studies have shown the marked differences in severity between a mild filtrate disease produced by swine influenza virus alone and the extensive pulmonary involvement when virus and *H influenzae suis* are combined (Shope, 1936). Moreover, in ferrets and mice it has been noted repeatedly that much more severe disease may occur in the presence of chronic bacterial infection of the animal, the pathologic pictures contain the basic viral lesions but they may be largely obscured by the extensive changes resulting from bacterial invasion.

Although the pathologic picture of influenza virus infection in man is clouded by bacterial complications, certain investigators of pandemic fatalities called attention to epi-

bronchiolitis or pneumonia may supervene. Since these conditions are commonly associated with bacterial infection, the pulmonary signs are influenced by the nature of the bacterium as are the x-ray findings In other instances, the temperature and the symptoms may have subsided, and the patient has begun to move about when a chill and sudden rise of temperature occur with a rapid return of symptoms Frequently, these episodes have been referred to improperly as relapses, as if of the primary illness, but they, too, usually represent the onset of bacterial pulmonary complications Leukocytosis develops, blood cultures may be positive, and examination of the sputum provides information of the complicating organism. The course will depend on the severity and the nature of the bacterial agent and the response to therapy Diffuse bronchopneumonia, lobar pneumonia, empyema or pneumothorax may occur In a small proportion of cases a fulminant pneumonia ensues. The patient may appear to have a characteristically mild illness for 1 or 2 days when, acutely, extreme dyspnea and prostration develop. Within a matter of hours the patient is dangerously ill and presents a shocked appearance with livid or heliotrope cyanosis, sweating, tachycardia, feeble pulse and low blood pressure. Temperature may fall below normal. Cough is feeble, and a thin serosanguinous fluid may exude from the respiratory tract. Instances have been noted in which fluid really ran from the lung when the head was placed in a dependent position The physical signs in the chest may be very misleading. Diffuse rales, more prominent at the bases, are heard; breath sounds are irregularly suppressed or perhaps exaggerated. The picture is really that of inflammatory pulmonary edema. Roentgenograms may reveal patchy opacities or a diffuse haziness in the lower lung fields The most common organism associated with the virus infection in these cases has been a coagulase positive staphylococcus pyogenes. Although acute staphylococcal infection of itself may produce a severe pneumonitis with diffuse involvement, in the presence of viral injury an additive effect occurs. Rapid deaths of somewhat similar clinical course also occur when other organisms are encountered In some instances no bacterial component has been identified, and in epidemics associated with virulent strains of virus it seems likely that virus alone may cause these severe illnesses as in experimental animals Persons with mitral stenosis appear to be especially vulnerable as if the development of alveolar fluid increased the probability of decompensation and further exaggeration of the pulmonary difficulty. Patients with other forms of advanced heart disease or chronic pulmonary fibrosis may tolerate the disease poorly.

Significant pneumonic complications among cases from the general population in usual epidemics scarcely exceed 1 per cent of the total. They are more frequent in young children and people over 50 years of age. In the epidemic of 1889-90 the incidence of pneumonia among cases of influenza was estimated to be 5 per cent But in the severe pandemic of 1918 it was still higher, and in certain military installations an incidence of 20 to 30 per cent of pneumonia was noted with a case fatality in some as high as 30 per cent (Jordan 1927; Hall, 1928). Moreover, in 1918 an excessively high frequency was noted in persons of 20 to 40 years of age, particularly among males Obviously, the increased incidence of influenza results in an increased frequency of pneumonia at all times

Influenza acquired during pregnancy often results in miscarriage or abortion. It seems probable that congenital defects are also increased There is an increased maternal and infant mortality so that influenza is a serious complication of pregnancy.

The clinical picture is essentially the same for influenza A and influenza B. The characteristics of influenza C are less clearly mapped, but on the basis of identified cases the presenting features are fever, headache, and coryza, which is more prominently mentioned than with other types (Francis et al., 1950; Taylor, 1951). On the other hand, the tendency of influenza C cases to be found in the midst of other identifiable influenza prevalences indicates the relative similarity in symptomatology to mild influenza. There are suggestions from volunteer studies that the incubation period may be as long as 5 to 7 days, although its development in the egg is similar in time to other strains (Quilligan et al., 1954).

The HVJ or Sendai virus infection, which

is now called influenza D, was first described as a form of severe pneumonitis in newborn infants (Sano et al, 1953). The prominent symptoms and signs were high fever, respiratory distress, cyanosis, rhinopharyngitis, leukocytosis; diffuse shadows were seen on roentgenograms. On the basis of volunteer experiments, an incubation period of about 48 hours was followed by sharp febrile response for 2 days, pulmonary shadows and a second febrile reaction about the 10th day (Kuroya et al, 1953). Of 9 sporadic infections noted in Scotland, 3 had pneumonia, the others were considered as influenza (Grist et al, 1957) In the Vladivostok epidemic among adults influenzalike illness occurred with fever commonly as long as 6 days, pulmonary involvement was seen as a complication without recorded fatalities (Gerngross, 1957)

PATHOLOGIC PICTURE

Most of the information as to the pathologic changes occurring in influenza of man is derived from fatal pneumonia cases in which bacterial invaders play a prominent role As a result, a great complexity of pictures is described from which the viral injury must be extrapolated However, studies in experimental animals with influenza viruses have resulted in a clear picture of the primary viral injury Influenza virus exerts a selective injury on the ciliated respiratory epithelium Within 48 hours after infection of a ferret with a well-adapted strain, the nasal respiratory epithelium is largely destroyed, leaving only the germinative basement membrane The adjoining olfactory and squamous epithelia are essentially unaffected (Francis and Stuart-Harris, 1938) Regeneration begins rapidly from the basement layer, and by the 6th day a transitional type of epithelium composed of polyhedral cells 3 to 4 layers deep is rather uniformly present Repair proceeds in the next week through stages of stratified squamous, hyperplastic columnar and the return of relatively normal ciliated columnar cells excreting mucus However, islands of cells which have not completely differentiated may still remain Studies of the lower respiratory tract have shown in ferrets (Francis, 1934, Shope, 1934, Brightman, 1936), swine (Shope, 1936), and mice (Straub, 1937) that the earliest lesion is the necrotizing damage to the respiratory ciliated epithelium The earliest injury may be more consistent in the bronchioles than in the trachea and the primary bronchi (Stuart-Harris, 1953). The epithelium of the terminal respiratory bronchioles is made [illegible] ... is undoubtedly influenced by the virulence of the strain

In ferrets and mice extensive pulmonary involvement develops about the hilum and extends peripherally, involving primarily the dependent lobes Entire lobes or even most of the lung may be affected The pleura is smooth, glistening and taut Grossly, the affected portions of the lung are distended and firm, purplish in color and filled with edema fluid Large amounts of serous fluid exude from the cut surface and from the bronchi, after which the tissue becomes wrinkled and rubbery

Microscopically, in addition to irregular epithelial necrosis, the alveolar walls are swollen, and the spaces are distended with edema fluid and hemorrhagic extravasations The cellular exudate is a scanty distribution of large pale-staining mononuclear cells There are hyperemia and edema of the bronchial and bronchiolar tunica Peribronchiolar collections of round cells are seen Necrotic exudate is present in the lumen There is dilatation of the blood vessels, edema of their walls and some perivascular cuffing The character of the pulmonary lesion is that of a profuse edema secondary to the epithelial injury rather than an acute inflammatory pyogenic pneumonitis With recovery, epithelial hyperplasia and regeneration proceed more slowly than in the turbinates Nodular hyperplastic overgrowths are prominent These pneumonias are bacteria-free and are clearly related to virus alone Shope's studies have shown the marked differences in severity between a mild filtrate disease produced by swine influenza virus alone and the extensive pulmonary involvement when virus and *H influenzae suis* are combined (Shope, 1936) Moreover, in ferrets and mice it has been noted repeatedly that much more severe disease may occur in the presence of chronic bacterial infection of the animal; the pathologic pictures contain the basic viral lesions but they may be largely obscured by the extensive changes resulting from bacterial invasion

Although the pathologic picture of influenza virus infection in man is clouded by bacterial complications, certain investigators of pandemic fatalities called attention to epi-

bronchiolitis or pneumonia may supervene. Since these conditions are commonly associated with bacterial infection, the pulmonary signs are influenced by the nature of the bacterium as are the x-ray findings In other instances, the temperature and the symptoms may have subsided, and the patient has begun to move about when a chill and sudden rise of temperature occur with a rapid return of symptoms. Frequently, these episodes have been referred to improperly as relapses, as if of the primary illness, but they, too, usually represent the onset of bacterial pulmonary complications Leukocytosis develops, blood cultures may be positive, and examination of the sputum provides information of the complicating organism. The course will depend on the severity and the nature of the bacterial agent and the response to therapy Diffuse bronchopneumonia, lobar pneumonia, empyema or pneumothorax may occur In a small proportion of cases a fulminant pneumonia ensues. The patient may appear to have a characteristically mild illness for 1 or 2 days when, acutely, extreme dyspnea and prostration develop Within a matter of hours the patient is dangerously ill and presents a shocked appearance with livid or heliotrope cyanosis, sweating, tachycardia, feeble pulse and low blood pressure Temperature may fall below normal Cough is feeble, and a thin serosanguinous fluid may exude from the respiratory tract Instances have been noted in which fluid really ran from the lung when the head was placed in a dependent position The physical signs in the chest may be very misleading. Diffuse rales, more prominent at the bases, are heard, breath sounds are irregularly suppressed or perhaps exaggerated The picture is really that of inflammatory pulmonary edema. Roentgenograms may reveal patchy opacities or a diffuse haziness in the lower lung fields. The most common organism associated with the virus infection in these cases has been a coagulase positive staphylococcus pyogenes Although acute staphylo- [illegible] infection of itself may produce a severe [illegible] the [illegible] occurs. Rapid deaths of somewhat similar clinical course also occur when other organisms are encountered In some instances no bacterial component has been identified, and in epidemics associated with virulent strains of virus it seems likely that virus alone may cause these severe illnesses as in experimental animals. Persons with mitral stenosis appear to be especially vulnerable as if the development of alveolar fluid increased the probability of decompensation and further exaggeration of the pulmonary difficulty. Patients with other forms of advanced heart disease or chronic pulmonary fibrosis may tolerate the disease poorly.

Significant pneumonic complications among cases from the general population in usual epidemics scarcely exceed 1 per cent of the total. They are more frequent in young children and people over 50 years of age. In the epidemic of 1889-90 the incidence of pneumonia among cases of influenza was estimated to be 5 per cent. But in the severe pandemic of 1918 it was still higher, and in certain military installations an incidence of 20 to 30 per cent of pneumonia was noted with a case fatality in some as high as 30 per cent (Jordan 1927; Hall, 1928). Moreover, in 1918 an excessively high frequency was noted in persons of 20 to 40 years of age, particularly among males. Obviously, the increased incidence of influenza results in an increased frequency of pneumonia at all times.

Influenza acquired during pregnancy often results in miscarriage or abortion. It seems probable that congenital defects are also increased. There is an increased maternal and infant mortality so that influenza is a serious complication of pregnancy.

The clinical picture is essentially the same for influenza A and influenza B The characteristics of influenza C are less clearly mapped, but on the basis of identified cases the presenting features are fever, headache, and coryza, which is more prominently mentioned than with other types (Francis et al, 1950, Taylor, 1951) On the other hand, the tendency of influenza C cases to be found in the midst of other identifiable influenza prevalences indicates the relative similarity in symptomatology to mild influenza There are suggestions from volunteer studies that the incubation period may be as long as 5 to 7 days, although its development in the egg is similar in time to other strains (Quilligan et al, 1954).

The HVJ or Sendai virus infection, which

alveolar walls which are not primarily affected by influenza virus Repair is much delayed, and fibrous replacement occurs Unfortunately, no cases of streptococcus pneumonia were investigated Sections from fatal cases of 1918 were also studied. Staining revealed staphylococci in 7 of the 8 instances where bacteria could be identified The character and the extent of epithelial degeneration

antly

was

gree

Hers also demonstrated that the epithelial lesions associated with influenza virus are also found in measles and varicella This similarity with measles was emphasized by MacCallum (1919) in studies of pneumonia associated with measles in 1917 See also Callender (1929)

Because of the concentrated attention given to the autumnal epidemic of 1957, numerous fatal cases were reported to the U S P H S A number of them were staphylococcal; from others no significant bacteria were recovered, although this feature is complicated by antibiotic therapy A significant proportion had mitral disease or were pregnant Extensive edematous pneumonia is described, sometimes with hyaline membranes (CDC Influenza Reports, 1957-58)

into the pancreas and the ovary have been considered not infrequent Hemorrhage into the adrenals occurs frequently in the presence of staphylococcal complications and may play a role in the picture of physiologic collapse Ordinarily, the central nervous system has displayed no evidence of primary injury Although encephalitis lethargica was prevalent in 1918, no causal relation to influenza virus has been shown

EXPERIMENTAL INFECTION, HOST RANGE

Although there had been earlier reports of the transmission of a virus from influenza of man to experimental animals, knowledge of its etiology begins with the demonstration that a virus could be transmitted intranasally to ferrets with filtrates of garglings from influenza patients Then the infection could be maintained in serial passage with extracts of ferret's turbinate tissue (Smith et al, 1933) Characteristically, after an incubation period of 48 hours there is an abrupt onset of fever with lassitude, sneezing, yawning, nasal discharge and loss of appetite. The eyes are congested, and the fur is ruffled or matted Virus is essentially localized in the nasal tissues Generally, the evidence of illness lasts no more than 4 to 5 days, the animal recovers rapidly and is immune to reinfection at that time Virus disappears, and specific antibodies rapidly appear in the blood If ferrets are etherized at the time of inoculation, the disease becomes progressively more severe in passage as the virus becomes adapted to the lungs with the production of extensive, often fatal, viral pneumonia (Francis, 1934). Virus is readily recovered from the lungs as well as from the nose. It has been noted that virus inoculation of ferrets which are maintaining a naturally acquired respiratory infection with β hemolytic streptococci or pasteurella may exhibit a form of disease still further enhanced by invasion of the existing bacterial pathogens Recovery from virus infection does not result in permanent immunity, and in a few months intranasal inoculation of the same virus may induce febrile illness with damage again to the nasal respiratory epithelium. Usually the lungs are not involved again

There is considerable difference in the capacity of different strains of Type A to elicit fever and clinical evidence of infection and in their adaptability to produce significant pulmonary disease Type B strains produce mild disease, generally, and become adapted slowly Multiplication of Type C strains appears to be limited to the turbinates, nevertheless, the development of antibodies reflects the infectious experience Limited experience with Type D (Sendai) virus resulted in fever, lung consolidation, and death with early ferret passages, but milder illness occurred in later passages (Jensen et al, 1955)

The various forms of influenza in the ferret closely resemble those of man They are highly susceptible and also produce high yields of virus Ferrets may become infected by natural exposure outside the laboratory, and this may

thelial degenerations at all levels of the respiratory tract apart from purulent necrotizing bacterial injury Moreover, they were noted in pneumonias associated with bacteria which do not ordinarily cause primary degeneration of ciliated epithelium Rapid regenerative hyperplasia and metaplasia were also commonly observed Thus, the epithelial lesion was suggested as characteristic of influenzal infection. In addition, 2 notable cases of 1918 were reported by Goodpasture and Burnett (1919) in which epithelial lesions were noted in the absence of demonstrable bacteria There can be little doubt, however, that a major part of the pneumonic pathology of 1918 was related to the nature of the bacterial component Its character varied in time and location of the study. Opie et al (1921) repeatedly emphasized the change in nature of the pulmonary disease in the course of the epidemic with the advent of a new bacterial pathogen and noted that the individual patient might suffer a succession of pneumonias. Hence, the features of lobar or lobular pneumococcal pneumonia and empyema, of *H. influenzae* interstitial bronchiolitis, of β hemolytic streptococcal interstitial suppurative bronchopneumonia and early serous empyema, of staphylococcal necrotizing bronchitis with miliary abscesses were commonly reported as preponderant in various areas The pathologic picture characteristic of a given bacterium became more prominent with the duration of the disease. But in a certain proportion of cases succumbing early in the disease there was what Winternitz et al (1920) called "acute, diffuse, influenzal pneumonia" The descriptions are striking The dependent portions of the lung are most frequently involved There

There may be little true consolidation Marked destruction of the tracheal and the bronchial epithelium is described. The bronchioles are distended and contain exudate, the alveolar walls are thickened Hemorrhage into the alveoli is prominent, but exudate is scanty and aplastic One feature was considered by some to be characteristic: the alveolar ducts are dilated and completely lined by a hyaline membrane in the center of which an air bubble can be seen Goodpasture (1919) showed that it did not take the fibrin stain It resembles a concentrated amorphous exudate pushed by respiration from the bronchioles against the surface of the alveolar walls The nature of *this material is* not known, but it has not been noted in experimental disease. This extremely acute picture was ascribed by different investigators to different bacterial agents, and that fact, of itself, indicates that the outstanding feature of extensive edema was probably a consequence of the basic viral injury as it is in experimental disease. Thereby the different organisms were provided a rich medium in which

fluence

cluded

fluenzal virus-pneumococcal pulmonary infection of rats

Since the identification of influenza viruses, studies of fatalities occurring during epidemic periods have been limited However, they have emphasized the fact that the majority of fatal cases with demonstrated influenza virus infection have been associated with coagulase positive *Staphylococcus aureus* (Scadding, 1937; Parker et al, 1946; Straub and Mulder, 1948; Mulder and Verdonk, 1949, Stuart-Harris et al., 1950; Hers and Mulder, 1951, 1953) Because of destructive effect of staphylococcal infection, query has been raised as to the relative importance of virus and coccus in production of the epithelial injury. Hers and Mulder (1951) and Stuart-Harris (1953) have reported recovery of virus from the lungs of fatal cases in which no epithelial lesions could be demonstrated On the other hand, Hubble and Osborn (1941) described the typical lesion in 2 cases dying during an epidemic in 1940, from whose lungs no bacteria were recovered This entire problem has been studied beautifully by Hers (1955) who has compared by detailed histologic and microbiologic technics the pathology in fatal cases of bacterial pneumonia of 4 to 12 days' duration, with or without associated influenza A viral infections He has demonstrated that epithelial degeneration does not occur with *H. influenzae* or pneumococcus unless influenza virus infection is also present The basal cell layer of the epithelium remains intact Interstitial extension in the bronchioles and the lung is largely absent, as also are hyperemia and edema and vascular thrombi. The same viral lesion occurs in conjunction with staphylococcus, but there the wounded epithelium becomes invaded, the basal layer is seriously damaged, and colonies of bacteria form abscesses in the tunica so as to push out plugs of exudate into the lumen Hyperemia, edema, hemorrhage and vascular thrombi are extreme Moreover, the destructive lesions extend into the respiratory bronchioles and

alveolar walls which are not primarily affected by influenza virus Repair is much delayed, and fibrous replacement occurs Unfortunately, no cases of streptococcus pneumonia were investigated Sections from fatal cases of 1918 were also studied Staining revealed staphylococci in 7 of the 8 instances where bacteria could be identified The character and the extent of epithelial degeneration and regeneration did not differ significantly between them and cases of 1949-53, nor was the hemorrhagic edema of different degree Hers also demonstrated that the epithelial lesions associated with influenza virus are also found in measles and varicella This similarity with measles was emphasized by MacCallum (1919) in studies of pneumonia associated with measles in 1917 See also Callender (1929)

Because of the concentrated attention given to the autumnal epidemic of 1957, numerous fatal cases were reported to the U S P H S A number of them were staphylococcal, from others no significant bacteria were recovered, although this feature is complicated by antibiotic therapy A significant proportion had mitral disease or were pregnant Extensive edematous pneumonia is described, sometimes with hyaline membranes (CDC Influenza Reports, 1957-58)

Significant pathologic changes in other organs have not been consistently observed, and when present their relation to associated bacterial infection is not readily assessed The vascular leakage observed with influenza virus infection does suggest that either directly or indirectly the virus has an effect on vascular permeability Certain hyaline muscular changes have been described Hemorrhages into the pancreas and the ovary have been considered not infrequent Hemorrhage into the adrenals occurs frequently in the presence of staphylococcal complications and may play a role in the picture of physiologic collapse Ordinarily, the central nervous system has displayed no evidence of primary injury Although encephalitis lethargica was prevalent in 1918, no causal relation to influenza virus has been shown

EXPERIMENTAL INFECTION, HOST RANGE

Although there had been earlier reports of the transmission of a virus from influenza of man to experimental animals, knowledge of its etiology begins with the demonstration that a virus could be transmitted intranasally to ferrets with filtrates of gargings from influenza patients. Then the infection could be maintained in serial passage with extracts of ferret's turbinate tissue (Smith et al, 1933). Characteristically, after an incubation period of 48 hours there is an abrupt onset of fever with lassitude, sneezing, yawning, nasal discharge and loss of appetite The eyes are congested, and the fur is ruffled or matted Virus is essentially localized in the nasal tissues Generally, the evidence of illness lasts no more than 4 to 5 days, the animal recovers rapidly and is immune to reinfection at that time Virus disappears, and specific antibodies rapidly appear in the blood If ferrets are etherized at the time of inoculation, the disease becomes progressively more severe in passage as the virus becomes adapted to the lungs with the production of extensive, often fatal, viral pneumonia (Francis, 1934). Virus is readily recovered from the lungs as well as from the nose. It has been noted that virus inoculation of ferrets which are maintaining a naturally acquired respiratory infection with β hemolytic streptococci or pasteurella may exhibit a form of disease still further enhanced by invasion of the existing bacterial pathogens Recovery from virus infection does not result in permanent immunity, and in a few months intranasal inoculation of the same virus may induce febrile illness with damage again to the nasal respiratory epithelium Usually the lungs are not involved again

There is considerable difference in the capacity of different strains of Type A to elicit fever and clinical evidence of infection and in their adaptability to produce significant pulmonary disease Type B [illegible]

development of antibodies reflects the infectious experience Limited experience with Type D (Sendai) virus resulted in fever, lung consolidation, and death with early ferret passages, but milder illness occurred in later passages (Jensen et al, 1955)

The various forms of influenza in the ferret closely resemble those of man They are highly susceptible and also produce high yields of virus Ferrets may become infected by natural exposure outside the laboratory, and this may

cause great difficulty in virus passage Their susceptibility to laboratory exposure to influenza virus and to distemper virus requires their strict isolation

Adaptation of influenza virus to mice was valuable for investigation (Andrewes et al, 1934, Francis, 1934) and diagnostic procedures Intranasal instillation of virus from ferret or man into lightly etherized mice and repeated passage at 2- to 3-day intervals with suspensions of mouse lungs commonly results in progressive adaptation of the virus to produce fatal pulmonary disease The time of death is a fair measure of the virus concentration administered With large doses of virus, deaths may occur in 2 to 3 days, with smaller amounts, in 10 to 14 days The lung lesions or fatality provide useful end points in demonstration of virus-neutralizing antibodies and for studies of pathogenesis and immunity The involved lungs are swollen, edematous and plum colored; the entire lung except for small emphysematous margins may be involved, grading to small lesions in nonfatal infection Highly adapted strains given intraperitoneally may cause pulmonary lesions, apparently by overflow from a transient viremia into the upper air passages (Rickard and Francis, 1938) After intravenous inoculation, virus may be recovered from the lung and appears to multiply without producing significant lesions, this apparently is related to the presence of virus on the vascular rather than the epithelial side of the vulnerable tissues. Although influenza virus can be isolated directly in mouse lung, its early recognition requires transfer to eggs Adaptation to produce suitable pulmonary lesions may be a slow process Influenza B strains are usually less virulent and have lower titers in mice than A strains. Studies of the growth curve of a well-adapted strain of Type A in mice have indicated a generation cycle of a few hours and the peak of virus production in 48 hours, thus preceding the development of pulmonary lesions (Taylor, 1941) Type C strains have not been adapted to the lungs of mice; as in ferrets, the virus remains limited to the turbinates Type D virus (Sendai) is a source of uncertainty. Japanese authors report its recovery from mice. With passage it produces fatal pulmonary disease, but death does not occur until about the 7th day, and virus titers are low. The WS strain of Type A virus became rapidly adapted to intracerebral virulence in mice and can be maintained as a neurotropic strain (Stuart-Harris, 1939, Francis and Moore, 1940).

Mice can be readily immunized by the intraperitoneal route with active or inactive virus Antigenic content of a vaccine may be quantitated by this procedure Subcutaneous vaccination is less effective. Recovery from infection gives immunity to a wide range of strains of the same type, but there is no specific cross immunity with other types

The chick embryo is a most susceptible host New strains are best isolated in the amniotic sac of 13- to 14-day embryos (Burnet, 1940; Beveridge and Burnet, 1946). Direct isolation can be made also by inoculation into the allantoic cavity, preferably of 9- to 10-day embryos, but this is a less sensitive procedure (Hirst, 1945). After a few amniotic passages most strains will propagate satisfactorily in the allantoic cavity The virus multiplies in the embryonic membranes and is given off into the extra embryonic fluids reaching infectious titers of 10^{-9} (Pearson, 1944) The virus also exhibits its characteristic tropism in the destruction of the respiratory epithelium of the

are incubated for 2 to 4 days, and the presence of virus is recognized by agglutination of erythrocytes. Ordinarily, about 10^6 infectious units are required to cause visible agglutination of erythrocytes The virus may be identified by the inhibiting action of specific immune serum Type C strains grow well in the amniotic sac but irregularly in the allantoic cavity

Strains that have been passed repeatedly often develop the capacity to cause death of the embryo in 2 to 3 days, the time of death is related to the concentration of virus However, the Asian strains of 1957 induced this from the start in a goodly proportion of embryos

Infection can be established on the chorioallantoic membrane or by injections into the yolk sac. These procedures are less satisfactory and are employed essentially for special purposes A de-embryonated preparation, i e, the membranes remaining in place after re-

moval of embryo and fluids, has proved to be of great value in studies requiring repeated measures of virus production (Bernkopf, 1950).

Influenza virus was first cultured in vitro, using the medium of Li and Rivers, i.e., minced chick embryo tissue in Tyrode's solution (Francis and Magill, 1935). Virus can be maintained in serial passage indefinitely and retains a significant pathogenicity for ferrets and mice. Tissue culture can also be used for initial isolation of virus from man. Minced embryo tissue on nutrient agar or in roller tubes can also be used (Pearson and Enders, 1941). In recent years whole chorio-allantoic membranes in balanced salt solution in a respirometer flask have been extremely useful in studying viral synthesis and its inhibition (Ackermann, 1951). In cultures of chick-embryo lungs or monkey kidney cells some strains have been observed to produce cytopathic injury with plaque formation (Ledinko 1955. Henry and Youngner, 1957). Use of the chorio-allantoic membrane in culture has provided additional evidence of the mucoid nature of virus receptors in that tissue, of their destruction by virus and their regeneration (Stone, 1948). Moreover, the release of virus has been demonstrated to proceed in a relatively continuous manner for hours rather than as an explosive burst, several generations may be released at intervals of 5 to 6 hours from the same tissue—although it is not certain they are from the same cells (Ackermann and Maassab 1954a). Nevertheless, the release from single cells is observed to occur over a period of time (Cairns, 1952). When large doses of virus are employed to introduce virus into all cells, the first release of virus occurs between 2 and 3 hours, it continues at a rapid rate for the next 7 hours, and by 12 hours is essentially complete, although lesser amounts of virus may be forthcoming for several hours later (Ackermann and Maassab, 1954a). The cells obviously are not rapidly destroyed. This relatively simple tissue behaves differently from the highly differentiated respiratory epithelium in that respect. The lag period of Type D virus is 6 to 7 hours in similar cultures, and the release is slower (Jensen et al., 1955, Ackermann and Maassab, 1954b).

Influenza viruses have been shown to damage respiratory epithelium maintained in cultures (Bang, 1958). Type D virus has been observed to produce cytopathic effect on cultures of human embryonic lung in roller tubes, while strains of other types did not (Gorbunova et al., 1957).

Infection can be induced experimentally in man by intranasal instillation of virus that has been maintained in ferrets, mice, or eggs. The nature of the illness differs little from that naturally acquired. Definite signs of pneumonitis may develop. It has been suggested that because of the large inoculum used some of the illness is a "toxic" reaction rather than infection. This is a dubious conclusion, for subjects given equal concentrations of inactivated virus do not exhibit signs or symptoms of illness, nor do those persons who resist the challenge with active virus. On the other hand, the PR8 strain passed in tissue culture was noted to be so attenuated as to excite no illness in adults, and antibody response was infrequent (Francis, 1940b, 1950). Both influenza A and influenza B have been experimentally induced in man by various investigators, this has been reviewed earlier (Francis 1950). An effort to incite influenza C in adults was not successful (Quilligan et al. 1954). Japanese investigators have reported the induction of disease in human subjects with Type D virus (Kuroya et al., 1953, Ishida 1957). Introduction of swine influenza virus, after repeated tissue culture, intranasally into a group of men caused little illness. Russian scientists have had extensive experience in experimental infection of volunteers in relation to the development and the use of active virus vaccine (Smorodintsev and Zhdanov 1957).

Swine have been a continued host for swine influenza virus. Shope has demonstrated that the characteristic disease seen in swine herds is a joint infection by virus and *H. influenzae suis*, although spread of the disease and immunity thereto is essentially related to the virus alone (Shope 1934, 1936). Shope has also described experiments indicating that the lung worm of hogs may be an intermediate host in which virus in a "masked" form is maintained between epidemics. The lung worm apparently becomes host to the virus when in the hog's lung. the larvae excreted onto the soil are ingested by earthworms and undergo additional stages of development

The earthworms are eaten by hogs, the lung worm larvae migrate from the alimentary tract to the lung, all this time retaining virus in a masked form demonstrable only when certain provoking stimuli—cold, various disturbing injections—break out the virus and incite influenza in the swine host (Shope, 1941a, b; 1943a, b, 1954). In other countries strains of virus more closely similar to other strains isolated from man have been recovered from swine influenza, and *H. influenzae* has been found less regularly Swine influenza virus was noted by Shope to produce pulmonary disease in mice and ferrets from the initial passage. Evidence has been gained of infection of swine in nature with Type A viruses prevalent in the human population at the time (Shope, 1938). Recovery from swine of the human epidemic strain of 1957 was reported from Japan (WHO bulletin). Type D virus has also been reported in outbreaks of disease in swine (Sasahara, 1955)

Types A and B viruses have been adapted to hamsters A number of other species, including certain squirrels, mink and chipmunks, have been shown to have a degree of susceptibility. Monkeys may show evidence of inapparent infection

Horse influenza has not been associated with viruses resembling the influenza group However, Sovinova et al (1957) have described an outbreak of respiratory disease in horses from which a virus related by complement-fixation test to Type A influenza virus was recovered Serologic studies revealed the development of specific HI as well as CF antibodies with recovery In HI tests no significant crossing with other strains of Type A has been noted The virus causes mild illness in ferrets after egg passage Antibodies in the human population of the U S A have not been demonstrated, but certain individuals recovering from Asian 1957 strains show low serologic crossing with this equine strain by complement-fixation tests (Maassab and Francis, 1958).

One factor which must be seriously considered when influenza viruses are said to be isolated from odd species of animals is possible laboratory contamination This has caused confusion in the past. If a presumedly new strain produces pulmonary disease in ferrets and mice from the start, it should be suspect. On the other hand, one may observe limited lesions in the lungs of animals when throat washings are inoculated, but they do not persist in the next transfers

ETIOLOGY

The primary causative agents are viruses of medium size At present the influenza viruses of human origin are divided into 3, probably 4, immunologically distinct serologic types, i e, A, B, C, D. Types A and B have been shown to comprise numerous variant strains which tend to group themselves serologically into families with closer resemblances among the familial members than to strains of the other groups. The virus of swine influenza described by Shope (1931) belongs to Type A; certain other strains recovered from infection in hogs have also been of Type A A classification on this basis might be as follows.

INFLUENZA VIRUS, TYPE A

Group	Prototype	Common Term	Prevalence
A_1	S15	Swine influenza	19— to 1928
A_2	PR8	Influenza A virus	1934-43
A_3	FM1	A prime virus	1946-57
A_4	Japan 305	Asian influenza	1957 (188?-189?)

The original WS strain of 1933 is difficult to classify; age distribution of antibodies in human population indicates that it is chronologically similar to PR8 Similar variations of Type B have been observed but less sharply distinguished. Nevertheless, 2 subgroups may be suggested·

INFLUENZA VIRUS, TYPE B

Group	Prototype	Common Term	Prevalence
B_1	Lee	Influenza B virus	1936-48
B_2	GL	—	1954-

These divisions are less certain, there are more intermediate strains as shown by age

distribution of antibodies, and the points of division may differ in various regions. The present division is based on the fact that vaccination with Lee strain was effective in epidemics of 1945 and 1952 but of limited influence in 1954-55.

There is no information of significant variants among Type C or D strains The type character is readily demonstrable by complement-fixation, and the strain or group variation within a type can be demonstrated best by other serologic procedures Cross-reactions between the types do not occur, but Schafer (1955) has reported crossing in complement-fixation with nucleic acid fractions of fowl plague virus and FMI strain of Type A influenza virus

Influenza viruses have been described as round or ovoid elementary bodies, discrete particles of relatively uniform size, measuring 80 to 120 mμ in diameter, Type B virus is somewhat larger than Type A (Elford et al, 1936, Sharp, Taylor et al, 1944, Friedewald and Pickels, 1944) Preliminary data suggest that Type D virus is of irregular size and may be 200 mμ in diameter (Hartman and Ackermann, 1954, Nishikawa and Fukumi, 1954) There are pleomorphic filamentous forms of influenza virus of 1 mμ or more, most commonly seen with newly isolated strains (Mosley and Wyckoff, 1946, Dawson and Elford, 1949). They have been detected in tissues infected with old passage strains as well (Wyckoff, 1951, Murphy and Bang, 1952) They can be observed in darkfield preparations, extensive studies of their formation by electronmicroscopy suggest that they are viral structures assuming different morphology as a result of some defect in their emergence through the cell wall Their infectious capacity is still uncertain, but they retain specific antigenic components They can be broken down into smaller units by physical and chemical procedures, and numerous suggestions have been made that the spherical bodies are so derived Morgan et al (1956) disagree sharply with that interpretation and consider the 2 forms as being independent, the spherical bodies they believe to be infectious and the filaments noninfectious Infectivity of virus preparations is lost following heating at 56° C for a few minutes, after ultraviolet irradiation, sonic vibration, treatment with formaldehyde, long-chain fatty acids and numerous other reagents Maximum stability of biologic properties is maintained between pH 6 5 and 7 9, their loss is more rapid in the acid range than in the alkaline The iso-electric point for the PR8 strain is pH 5.3 (Miller et al, 1944). As with many other agents, they are vulnerable to physiologic saline, but the addition of various proteins makes a relatively stable medium Purified preparations, properly buffered, may be held at 4° C for a month without showing marked reduction in titer Virus in allantoic fluid may be similarly maintained Ordinary freezing is harmful, but suspensions stored at −70° C for many months maintain their titer, especially if stored in sealed glass ampules The viruses are also well preserved when dried in vacuo

Influenza viruses display a variety of activities Foremost of these is infectivity which exhibits a selective affinity for epithelial cells of the respiratory tract in all affected species The effect is most consistent in damage to the nasal respiratory cells, but with well-adapted, virulent strains it extends to the ciliated respiratory epithelium of the trachea and the bronchial tree The WS strain has been shown to be adaptable as well to the brain in mice (Stuart-Harris, 1939, Francis and Moore, 1940) Certain strains exhibit the capacity to produce fatal hemorrhagic disorder of chick embryos, indicating an effect upon the vascular endothelium Ivanovics et al (1954) have reported the adsorption and the elution of virus from the vascular endothelium of guinea pigs, rats and mice However, influenza virus is essentially a pneumotropic agent

Influenza viruses were the first among animal viruses to be shown to possess the capacity to cause agglutination of red blood cells (Hirst, 1941, McClelland and Hare, 1941) Others, including mumps, Newcastle disease and fowl plague viruses, behave similarly Hemagglutination is the result of the interaction of the virus and the surface of erythrocytes, the second reaction is the agglutination of red-cell-virus complexes, the third is the spontaneous disassociation of the virus from the red cells Apparently a single virus particle may cause clumping between 2 erythrocytes (Horsfall, 1954) Hirst (1942) demonstrated that the virus released from the cells retains its hemagglutinating capacity

The earthworms are eaten by hogs, the lung worm larvae migrate from the alimentary tract to the lung, all this time retaining virus in a masked form demonstrable only when certain provoking stimuli—cold, various disturbing injections—break out the virus and incite influenza in the swine host (Shope, 1941a, b; 1943a, b; 1954). In other countries strains of virus more closely similar to other strains isolated from man have been recovered from swine influenza, and *H. influenzae* has been found less regularly Swine influenza virus was noted by Shope to produce pulmonary disease in mice and ferrets from the initial passage. Evidence has been gained of infection of swine in nature with Type A viruses prevalent in the human population at the time (Shope, 1938) Recovery from swine of the human epidemic strain of 1957 was reported from Japan (WHO bulletin) Type D virus has also been reported in outbreaks of disease in swine (Sasahara, 1955).

Types A and B viruses have been adapted to hamsters. A number of other species, including certain squirrels, mink and chipmunks, have been shown to have a degree of susceptibility Monkeys may show evidence of inapparent infection

Horse influenza has not been associated with viruses resembling the influenza group However, Sovinova et al. (1957) have described an outbreak of respiratory disease in horses from which a virus related by complement-fixation test to Type A influenza virus was recovered. Serologic studies revealed the development of specific HI as well as CF antibodies with recovery In HI tests no significant crossing with other strains of Type A has been noted. The virus causes mild illness in ferrets after egg passage. Antibodies in the human population of the U S A have not been demonstrated, but certain individuals recovering from Asian 1957 strains show low serologic crossing with this equine strain by complement-fixation tests (Maassab and Francis, 1958).

One factor which must be seriously considered when influenza viruses are said to be isolated from odd species of animals is possible laboratory contamination This has caused confusion in the past. If a presumedly new strain produces pulmonary disease in ferrets and mice from the start, it should be suspect. On the other hand, one may observe limited lesions in the lungs of animals when throat washings are inoculated, but they do not persist in the next transfers.

ETIOLOGY

The primary causative agents are viruses of medium size. At present the influenza viruses of human origin are divided into 3, probably 4, immunologically distinct serologic types, i e., A, B, C, D Types A and B have been shown to comprise numerous variant strains which tend to group themselves serologically into families with closer resemblances among the familial members than to strains of the other groups The virus of swine influenza described by Shope (1931) belongs to Type A; certain other strains recovered from infection in hogs have also been of Type A. A classification on this basis might be as follows.

INFLUENZA VIRUS, TYPE A

GROUP	PROTOTYPE	COMMON TERM	PREVALENCE
A_1	S15	Swine influenza	19— to 1928
A_2	PR8	Influenza A virus	1934-43
A_3	FM1	A-prime virus	1946-57
A_4	Japan 305	Asian influenza	1957 (188?-189?)

The original WS strain of 1933 is difficult to classify; age distribution of antibodies in human population indicates that it is chronologically similar to PR8 Similar variations of Type B have been observed but less sharply distinguished Nevertheless, 2 subgroups may be suggested:

INFLUENZA VIRUS, TYPE B

GROUP	PROTOTYPE	COMMON TERM	PREVALENCE
B_1	Lee	Influenza B virus	1936-48
B_2	GL	—	1954-

These divisions are less certain, there are more intermediate strains as shown by age

is not infective; it does not cause hemagglutination, nor does it elicit immunity. The antigen is common to all strains of a given type but does not cross with those of other types. Antibody to the soluble antigen develops generally only after infection. The use of complement-fixation with soluble antigen has certain distinct advantages in diagnostic work, especially for identification of the type of virus when strains of aberrant antigenic character are encountered. It possesses possible theoretical advantages in the diagnosis of illness in vaccinated persons when interpretation of hemagglutination-inhibition results may be complicated by antibodies derived from vaccination.

Strains of Types A and B cause a toxic injury following intracerebral, intraperitoneal or intravenous injection of virus in mice, guinea pigs, rabbits, rats and hamsters (Henle and Henle, 1946a, b). The toxic property cannot be separated from the infective property; toxic activity is not the result of virus multiplication. Toxic activity is directly correlated with virus concentration. Intraperitoneal or intravenous injection in mice may cause death in from 8 to 96 hours. The toxic effect of influenza A virus preparations is neutralized by anti-influenza A serum but not by anti-B virus serum, and vice versa. Moreover, vaccination of mice by either the subcutaneous or the intraperitoneal route causes them to become specifically immune against the toxic effects of the same serologic type. The toxic property remains stable on storage at 4° C. for 2 or 3 months and is inactivated by heating, treatment with formaldehyde or irradiation with ultraviolet light at a rate slower than the infectivity. It is thought that the virus particle itself carries the toxic property (Henle and Henle, 1946b).

Another form of toxic reaction is observed after subcutaneous injection in man, its severity is directly related to the amount of virus (Salk, 1948, Quilligan et al., 1948). The reaction occurs with inactivated virus. It is most severe in young children who may have high fever, chills and mild delirium. There is usually well-marked inflammatory reaction at the site of injection. In experimental animals it behaves as a pyrogen, small amounts may desensitize the animal so that later it will tolerate otherwise fatal doses.

Consideration of the formation of influenza virus has sought to explain the origins and the nature of the hemagglutinin and the soluble antigen. Study of the development and the growth of virus has revealed a period after virus enters the cell when it apparently loses its identity followed, after an interval of 2 to 3 hours, by the appearance in tissues of soluble antigen and hemagglutinin which is not infectious, while mature infectious virus appears later. When large amounts of virus are used to inoculate the membranes in deembryonate eggs or tissue cultures (Bernkopf, 1950, Henle and Girardi, 1955), the virus produced has relatively high hemagglutinating titer but a low infectious titer. It appears that virus has been produced in a form whose functional development is incomplete. Von Magnus (1947) originally observed this phenomenon, repeated passage with high-titer inoculum resulted in a progressive reduction of infectious virus while hemagglutinin titers remained high. Extensive study of the phenomenon has not provided full explanation, but it seems certain that overloading of the available cells and the presence of noninfectious virus in the inoculum play a role in incomplete formation of virus material. In fact, it seems likely that most virus yields contain particles of that nature. They are not infectious and probably not effective immunizing antigens. However, they do combine with cells and of themselves may restrict the yield of complete virus. Soluble antigen is also produced in large amounts. This area of investigation has been reviewed extensively (Henle, 1953, Von Magnus, 1954, Finter et al., 1955). Hoyle, in his analysis, has concluded that the virus particle after treatment with ether is disrupted with the liberation of 2 smaller particles. (1) the "soluble" antigen, contains essentially all the ribonucleoprotein (5.3 per cent RNA), or about 14 per cent of the weight of the infective particle, (2) the hemagglutinin is considered a mucoprotein, totaling 13 per cent of the particle, with the protein carrying the combining group having affinity for cells and also possessing the enzymic activity. It was estimated that 38 per cent was nonprotein material, 3.5 per cent of it carbohydrate, and 34.5 per cent lipid; in addition, 34 per cent other protein is com-

while the cells can no longer combine with the same or closely related strains. The fact that different viruses may combine with cells previously acted upon by a given virus gave rise to the effort to classify them in a "receptor gradient" series (Burnet et al, 1946) The cells are altered so that they migrate differently in an electrophoretic field (Hanig, 1948) Hirst emphasized the enzymatic nature of the reaction and that the substrate was a mucoprotein on the surface of the erythrocytes He showed that virus is adsorbed and subsequently released spontaneously from the cells of the excised ferret lung (Hirst, 1943). Attachment and enzymatic effects have been observed with mouse lung tissues, chorio-allantoic membrane, vascular endothelium of different species; virus combines with leukocytes *in vitro* and reduces their phagocytic capacity (Merchant and Morgan, 1950) Recent study has shown that virus particles are themselves phagocytized by leukocytes (Boand et al, 1957; Hanson et al, 1957) The suggestion from all these observations is that the enzymatic activity is an essential component of the process by which influenza virus gains entry to the susceptible mucus-producing respiratory epithelium to establish infection.

Interference is demonstrable with influenza as with many other viruses It is apparently related to the saturation of receptor sites or essential metabolic processes by one strain *so that another cannot be satisfactorily established* in the same cells Interference has been demonstrated in tissue cultures, eggs, mice and ferrets Cross-effect between Type A and Type B strains has been demonstrated, but this may be overcome by increasing the amount of the second virus. Large amounts of virus rendered noninfectious by ultraviolet light may establish interference. The effect is apparently induced by the virus particle itself Interference between influenza and a number of other viruses has been demonstrated The subject has been reviewed by Henle (1953) Recent studies purport to indicate that a product of cell-virus interaction called "Interferon" plays a role in interference (Lindemann et al, 1957).

Studies of virus-cell interaction have revealed the occurrence of numerous mucoproteins in body fluids or tissues and in ovo*mucin which react with the virus and inhibit* its combination with erythrocytes in vitro They appear to represent the normal substrate upon which these viruses act The inhibitors are destroyed by continued exposure *to the active* virus, leaving the virus again able to act in a normal manner (Hirst, 1942a). If virus is heated at 56° C. to de*stroy infectivity, the capacity to* combine with red cells and agglutinate them is not impaired, although the heated virus will not elute from the cells. The agglutinating activity of heated virus is prevented by high dilutions of inhibitors such as those found in normal sera (Francis, 1947). Heating has not destroyed the capacity to combine with varied mucoproteins but has eliminated the enzymatic action which permits the splitting of the mucoprotein inhibitor in the serum or on the receptor sites of the erythrocyte. The material, which some have termed α inhibitor, migrates with the alpha globulins in electrophoresis (Tyrrell, 1954). This phenomenon is considered in detail in Chapter 4 Another inhibitor in serum is heat labile, neutralizes infectious virus and appears to be part of the natural defense mechanism This was studied by Ginsberg and Horsfall (1949) and corresponds to the labile inhibitor initially observed by Hirst (1942b)

When influenza virus and immune serum against it are mixed and red cells are then added, hemagglutination is specifically pre*vented by antibody (Hirst, 1942b)*. The immune serum can be diluted to an extent proportional to its virus-neutralizing titer before its capacity to inhibit hemagglutination by a constant amount of virus is exceeded This is the basis for the hemagglutination-inhibition test for antibodies which is described in Chapter 10. But it has also provided a most valuable set of reagents for detailed study of virus behavior, antigenic constitution and *im*munity

Complement is fixed by the interaction between virus particles and immune serum. The complement-fixing viral antigen exhibits a significant strain or group specificity (Friedewald, 1943). In addition there is a "soluble" antigen of much smaller size, 10 mμ (Lennette and Horsfall, 1940), first so designated by Hoyle and Fairbrother (1937) in preparations from infected mouse lungs The material

strains and give cross-reactions detectable by hemagglutination or neutralization tests The dominant antigen of one strain can be detected as a lesser antigen of another On this basis the hypothesis is advanced that strains of a given type comprise essentially the same antigens in limited number and that strain variation represents rearrangement of these antigens quantitatively or spatially (Magill and Francis, 1938, Smith and Andrewes, 1938, Francis, 1952, 1955, Salk, 1952) Strains prevalent in certain years will thus exhibit relationships with those of other times The bulk of evidence obtained by antigenic analysis of virus strains—especially by antibody absorption and multiple comparison—supports this view (Jensen and Francis, 1953, Isaacs et al, 1954) Limited comparisons by testing strains against single prototype sera provide an inadequate measure of strain relationships Studies of antibody patterns in the human population also emphasize the antigenic overlapping Younger persons exhibit antibody directed against the most prominent antigens of the strains they have encountered and retain their susceptibility to components which may dominate other antigenic complexes but have not been well represented in the antibody response to earlier strains With advancing age a broader immunity is reflected in the multivalent antibody acquired by contact with numerous primary and secondary antigens in strains encountered through the years (Davenport et al, 1953) If a ferret has been infected successively by 3 distinctive strains of Type A, absorption of the final serum with the initial strain will remove antibody to all while absorption with the 2nd or the 3rd infecting strain removes primarily antibody to the homologous strain and some of the heterologous antibody (Jensen et al, 1956) Essentially all Type A antibody can be removed from human serum by absorption with the strain prevalent during the childhood of different age groups These data emphasize the sharing of antigens between strains of different periods

Another view of antigenic variation has been that during the prevalence of a strain the population becomes immunized to its characteristic antigen so as to limit that strain's propagation, this dominant antigen is then eliminated in succeeding strains and replaced by an entirely new antigenic component (Andrewes, 1950, 1957) There is, according to this thesis, an orderly progression of variation by antigenic replacement which propels the pattern of mutation in one direction It tends to ignore the relationships which have been clearly demonstrated even between major variants of a type, as between swine influenza virus and the PR8 strain of 1934, between PR8 and the FM1 (A-prime) strain of 1947, and apparently between the A-prime strains of 1956-57 and the Asian variant of 1957 Gamma globulin prepared in 1943 had significant titers against the A-prime strains of 1947 and later, it also contained antibody to Type B strains of 1945 and 1952 (Davenport et al, 1953) Recent evidence that persons of more than 40 years of age, particularly over 70 years, display antibody to the Asian strains of 1957 (Mulder and Masurel, 1958) illustrates the return to primary position in current strains of antigens which had dominated strains of many years previous and in the meantime had probably persisted as secondary antigens Unpublished data by investigators in other countries have noted this occurrence of antibodies to Asian strains Autre temps, meme chose In opposition to the thesis of orderly and progressive replacement is the evidence that among groups of Type A strains in two successive 10 year periods, antigenic variation was a random affair rather than a chronological progression (Jensen and Peterson, 1957)

While it is currently believed that the nucleoprotein, type-specific, antigen carries the genetic determinants of the virus, the antigens represented in the hemagglutinin appear to play a dominant role in serologic and immunologic variation Variation has been observed to occur under different laboratory conditions of passage in mice, eggs, or tissue culture and on partial neutralization with immune serum in chick embryos Antigenic variants of the PR8 virus were obtained by Gerber et al (1956) by serial passage in the lungs of mice immunized with the homologous agent The variants exhibited a progressively decreasing reactivity with the parent PR8 antiserum but retained the capacity to induce antibody to PR8

Variation can be induced experimentally by recombination in which virus particles of

bined with the lipid and carbohydrate. Thus, the virus particle is pictured as developing "by fragmentation of the cell cytoplasm and that it consisted of a closely packed aggregate of soluble antigen and hemagglutinin enclosed in a membrane derived from the cell wall The chemical results would suggest that this membrane is composed of lipoprotein and mucoprotein *Treatment with ether denatures* the lipoprotein and disrupts the particle" Much of the lipid remains in the ether fraction (Frisch-Niggemeyer and Hoyle, 1956) *It is suggested that the RNA of the soluble* antigen is the fundamental replicating nucleoprotein of influenza virus Studies with P^{32} indicated that the virus nucleoprotein rapidly becomes associated with the cell nucleus (*Hoyle and Frisch-Niggemeyer, 1955*) This may be in keeping with the observations, using fluorescent antibody, that virus staining first appeared in cell nuclei due to the presence of soluble antigen (Watson and Coons, 1954, Liu, 1955) The structure of *fully formed virus is considered to* be a central core of type-specific nucleoprotein surrounded by strain-specific mucoprotein bound together by lipoprotein and mucoprotein, possibly derived directly from the cell These components may correspond to the inner body, the dense membrane and diffuse outer coat of active virus particles revealed by electronmicroscopy (Morgan et al, 1956) Serologic evidence strongly indicates that the dominant antigen is superficially located. It is not known which components are the essential factors in endowing virus with infectivity, but evidence from many sources suggests that this is acquired at or near the time of release through the cell surface Ada and Perry (1956) found no consistently proportionate relation between infectivity and nucleoprotein, but the possibility exists that this is an important factor in virus maturation It may be that large inocula, including inactive virus, use up the mucoprotein substrate of the cell necessary for this transformation, even as sulfonic acid prevents the release of influenza virus from infected cells (Ackermann and Maassab, 1954c). Although the failure of developing virus to gain completion *has not yet been explained* satisfactorily, the fact that the various reacting materials can be identified serologically as independent components makes easier consideration of the idea that their production may be proceeding in cells without attaining full viral configuration or, conversely, resulting from disruption of larger structural *units—including inactivated* virus

Serologic behavior of influenza virus can be related to the identified components *Complement-fixing type-specific antigen is a* ribonucleoprotein common to strains of Type A but differing from that of Type B. This material represents the soluble antigen and seems also to be the type-specific complement-fixing antigen in whole virus particles The hemagglutinin, a mucoprotein, exhibits strain-specific behavior which is characteristically inhibited by immune serum *It* is antigenic and induces protection of susceptible animals comparable with that attained with the virus *particles themselves* Antiserum to this fraction contains neutralizing antibodies The hemagglutinating component appears also to be the strain-specific complement-fixing anti*gen of the virus particle. The hemagglutinat*ing antigen can be absorbed by red cells from a preparation of disrupted virus, leaving the soluble antigen in relatively pure state (Frisch-*Niggemeyer and Hoyle, 1956*).

Within the *2* most studied types of influenza virus, A and B, numerous strains have been found to differ from one another serologically and immunologically, while retaining demonstrable similarities The variants within Type A strains, for example, tend to fall into subgroups or families This subject was reviewed by Jensen (1957) By selective procedures some difference can be detected between almost any 2 strains, indicating that serologic variation is a continuous phenomenon Vaccination of man has provided major information as to the immunologic significance of variants which have come into distribution. The differences are most distinct when sera prepared by single injection of nonsusceptible animals are employed in cross-hemagglutination or neutralization tests The similarities are demonstrated best in serum of man or other susceptible animals recovering from infection, or after hyperimmunization of susceptible or refractory species The results indicate that in addition to a common soluble antigen, individual strains contain a number of antigens which exist also in other

true when illness of that type represents a distinct change from the character of illness which has previously been occurring in institutional or other congregations continuously under observation. There is no clinical basis at present to differentiate influenzas A, B, C and D. Since the onset of numerous illnesses may superficially resemble influenza, and numerous transient illnesses pass by without clinical need for etiologic diagnosis, danger exists that the diagnosis of influenza will be made as a substitute for more exacting differentiation. Except in special circumstances, the effort and the expense required for laboratory confirmation is scarcely warranted in the sporadic suspect. However, when cases occur en masse, further study is recommended; there are at present numerous facilities for assistance which should be called upon. Details of laboratory diagnostic procedures are given in Chapter 10 by Jensen (1956) and by Lepine (1954).

The two procedures of most specific diagnostic worth are the isolation of virus from the patient and the demonstration of antibody rise in the serum of the patient to a type of influenza virus. Isolation of virus from throat washings of the acutely ill patient is the most rapid procedure. Optimally, the material should be obtained in the first 3 days of illness by having the patient gargle thoroughly and repeatedly with small amounts of broth, distilled water, or skimmed milk to a total volume of 15 to 20 ml. The gargling are collected in a clean stoppered container and taken to the laboratory where they are promptly injected, after addition of penicillin and streptomycin, into the amniotic sac of 10- to 14-day embryonated chicken eggs (Burnet, 1940) or frozen at −72° C. Nasal washings can be used as well. The fluids are harvested after 2 to 4 days of incubation and tested by hemagglutination for presence of virus. If present, virus can also be identified promptly by appropriate immune serum, and thus an unequivocal diagnosis may be established promptly. The percentage of virus isolations varies from one outbreak to another and with technical competence, but 80 per cent recovery is not unusual. Allantoic inoculation is easier but less sensitive, although Type B strains may be recovered with equal frequency by this method. After initial isolation in amniotic sac, most strains of Types A and B can be passed satisfactorily by the allantoic route, but Type C strains require amniotic transfer. Variation in the agglutination reaction with cells of different species may also be of presumptive value in identification as follows:

Virus Type	4° C Cells		22° C Cells	
	Chick	Guinea Pig	Chick	Guinea Pig
A	±	+	±	+
B	+	+	+	+
C	+	−	−	−
D	+	+	+	+

Human O cells are commonly used and behave similarly to guinea pig cells.

Isolation of virus by intranasal inoculation of ferrets is also highly efficient with strains encountered during well-marked epidemics of influenza A, but in lesser prevalences the clinical manifestations induced in the ferret may be irregular. Virus can commonly be recovered from the turbinates and transferred to eggs. Serologic tests with sera of the recovered ferret will confirm the nature of the virus infection, even though clinical signs are absent. Type B strains are decidedly less pathogenic for the ferret than those of Type A. Type C strains produce infection essentially localized in the turbinates without significant febrile reaction. Isolation of Type D virus in ferrets has not been reported.

Influenza virus can be transmitted directly from human throat washings to mice and hamsters, but its adaptation is slow. Type-C virus is not readily established in mice, although its isolation in that species has been reported (Fukumi et al., 1951).

The use of tissue culture in virus isolation

tion of Type A virus (Vogel and Shelekov, 1957).

Various authors have reported the value of cytologic studies of respiratory excretions from patients for influenzal diagnosis, the presence of injured epithelial cells is said to be diagnostic. Similarly, examination of scrapings from the trachea of the infected chick embryo has been used. The use of fluorescent

2 different strains effect combination of distinguishing properties of one strain with others of a second strain (Burnet and Lind, 1951) Gotlieb and Hirst (1954) have shown the derivation of serologically mixed strains after double infection of embryonate eggs Similar results have been obtained by using ultraviolet irradiated virus of one strain and active virus of another (Baron and Jensen, 1955). The development of this field can be of great theoretical and practical interest (see Jensen, 1957)

Variation in the avidity with which strains are neutralized by antibody is observed Van der Veen and Mulder (1950) have classified them in P, Q and R phases according to their behavior in the hemagglutination-inhibition reaction with convalescent ferret serum The P-phase virus is inhibited to high titer by its homologous serum only Q-phase virus is poorly neutralized even by homologous serum, while the R phase is inhibited to high titer by homologous sera and by sera against heterologous but related strains They may be altered by passage in mice or in eggs, but the explanation of their behavior is not well understood It may be related to location of antigens (Isaacs et al, 1954), the content of primary and secondary antigens, or even to the content of lipid components which may interfere with serologic reactions Newly isolated strains are commonly in P phase, but distinct exceptions are encountered and Q-phase behavior is encountered not infrequently Considerable differences exist in the extent to which hemagglutination by strains is prevented by nonspecific inhibitors in sera This is encountered with newly isolated strains and can cause confusion in serologic identification, especially if the strains are poorly neutralized by specific antibody.

Newly isolated strains often agglutinate guinea pig erythrocytes better than those of the chicken, but after passage in eggs this tendency may disappear, O-D variation (Burnet and Bull, 1943). Type B strains show this effect less than strains of Type A. Type C strains do not agglutinate guinea pig cells and act on chicken or human O cells best at refrigerator temperature (Taylor, 1951; Minuse et al, 1954) According to Hirst (1950), they act upon a receptor site on the erythrocytes' surface differently from that of other members of the species The Sendai Type D virus adsorbs and elutes rapidly from erythrocytes so that it may be necessary to read hemagglutination tests in 30 minutes.

Strains differ in their virulence and adaptability to experimental animals Certainly epidemic distribution and virulence are not necessary accompaniments, since a mild strain may be widely dispersed Alteration in antigenic composition may be an important asset but is not necessarily associated with high virulence Epidemic spread is undoubtedly related to enhanced affinity for susceptible cells, one may ask whether an exaggerated tendency to combine with nonspecific inhibitors may reflect the enhanced affinity for mucoproteins of the respiratory tissues and thus identify the epidemic character. The epidemic strain, well adapted to man, probably requires a smaller inoculum and has a more rapid growth curve than strains of limited extension, as is seen among strains adapted to new species experimentally (Wang, 1948, Davenport and Francis, 1951)

Influenza virus infection has a distinct influence in promoting bacterial invasion In experimental animals, pre-existing bacterial infection is activated to produce more severe disease. *Introduction of bacteria and virus* simultaneously is less disturbing except with swine influenza But introduction of organisms of low virulence after establishment of virus infection enhances their virulence as shown by subsequently retained characteristics (de Torregrose and Francis, 1941) The association between virus and staphylococcus in severe human disease is of interest because each exerts a necrotizing action The invasion of the virus-damaged tissue by staphylococci, producing deep tissue destruction, has been likened to wound infection

DIAGNOSIS

The diagnosis of influenza can be suspected on clinical grounds by exclusion or by careful observation of the individual case. When acute febrile illnesses of abrupt onset and 3 to 4 days' duration begin to occur in rapid succession without signs or symptoms representative of other recognizable disease, influenza should be suspected This is particularly

true when illness of that type represents a distinct change from the character of illness which has previously been occurring in institutional or other congregations continuously under observation. There is no clinical basis at present to differentiate influenzas A, B, C and D. Since the onset of numerous illnesses may superficially resemble influenza, and numerous transient illnesses pass by without clinical need for etiologic diagnosis, danger exists that the diagnosis of influenza will be made as a substitute for more exacting differentiation. Except in special circumstances, the effort and the expense required for laboratory confirmation is scarcely warranted in the sporadic suspect. However, when cases occur en masse, further study is recommended; there are at present numerous facilities for assistance which should be called upon. Details of laboratory diagnostic procedures are given in Chapter 10 by Jensen (1956) and by Lepine (1954).

The two procedures of most specific diagnostic worth are the isolation of virus from the patient and the demonstration of antibody rise in the serum of the patient to a type of influenza virus. Isolation of virus from throat washings of the acutely ill patient is the most rapid procedure. Optimally the material should be obtained in the first 3 days of illness by having the patient gargle thoroughly and repeatedly with small amounts of broth, distilled water, or skimmed milk to a total volume of 15 to 20 ml. The garglings are collected in a clean stoppered container and taken to the laboratory where they are promptly injected, after addition of penicillin and streptomycin, into the amniotic sac of 10- to 14-day embryonated chicken eggs (Burnet, 1940) or frozen at −72° C. Nasal washings can be used as well. The fluids are harvested after 2 to 4 days of incubation and tested by hemagglutination for presence of virus. If present, virus can also be identified promptly by appropriate immune serum, and thus an unequivocal diagnosis may be established promptly. The percentage of virus isolations varies from one outbreak to another and with technical competence, but 80 per cent recovery is not unusual. Allantoic inoculation is easier but less sensitive, although Type B strains may be recovered with equal frequency by this method. After initial isolation in amniotic sac, most strains of Types A and B can be passed satisfactorily by the allantoic route, but Type C strains require amniotic transfer. Variation in the agglutination reaction with cells of different species may also be of presumptive value in identification as follows:

Virus Type	4° C Cells: Chick	4° C Cells: Guinea Pig	22° C Cells: Chick	22° C Cells: Guinea Pig

B	+	+	+	+
C	+	−	−	−
D	+	+	+	+

Human O cells are commonly used and behave similarly to guinea pig cells.

Isolation of virus by intranasal inoculation of ferrets is also highly efficient with strains encountered during well-marked epidemics of influenza A, but in lesser prevalences the clinical manifestations induced in the ferret may be irregular. Virus can commonly be recovered from the turbinates and transferred to eggs. Serologic tests with sera of the recovered ferret will confirm the nature of the virus infection, even though clinical signs are absent. Type B strains are decidedly less pathogenic for the ferret than those of Type A. Type C strains produce infection essentially localized in the turbinates without significant febrile reaction. Isolation of Type D virus in ferrets has not been reported.

Influenza virus can be transmitted directly from human throat washings to mice and hamsters, but its adaptation is slow. Type-C virus is not readily established in mice, although its isolation in that species has been reported (Fukumi et al., 1951).

The use of tissue culture in virus isolation has been studied inadequately but is worthy of more consideration. Viruses of various types can be recovered by such procedures. Recently, studies of virus isolation in cultures of monkey kidney cells, using added guinea pig erythrocytes as indicator, have been reported to yield efficient results and rapid identification of Type A virus (Vogel and Shelekov, 1957).

Various authors have reported the value of cytologic studies of respiratory excretions from patients for influenzal diagnosis, the presence of injured epithelial cells is said to be diagnostic. Similarly, examination of scrapings from the trachea of the infected chick embryo has been used. The use of fluorescent

antibody to detect virus in nasal secretions has been proposed (Liu, 1955a). Detection of hemagglutinins in throat washings or assay of normal inhibitors has also been studied as means of rapid diagnosis but has not been found to be generally suitable.

Serologic diagnosis is based on the fact that recovery from influenza virus infection is accompanied by the development of antibodies to the virus They may be detected 5 to 7 days after onset and reach their peak in 12 to 14 days Since a significant proportion of the population, especially adults, may possess demonstrable antibodies as a result of earlier experience with related strains, it is essential that 2 specimens of sera be obtained, one in the early acute phase and another in convalescence, for comparative titrations of antibody level. Little or no antibody may be present in the initial specimen from children or in that of older persons when strains differing sharply from those of earlier prevalences are encountered Under other circumstances moderate antibody titers may be encountered at the time of onset The convalescent level of antibody is then evaluated in relation to the initial titer. A significant rise in antibody must exceed the margin of error of the technical procedure The methods in general use are reasonably accurate within a 2-fold variation A rise from no demonstrable antibody in the lowest dilution of serum to an extent that 2 or more higher dilutions exhibit an antibody effect against a specific type of influenza virus or strain can, therefore, be considered significant In the presence of antibody initially present, a specific 4-fold rise is usually acceptable Commonly, the increases are greater.

may be noted in persons recently vaccinated whose sera are tested with the vaccinating strains. However, when tested against the epidemic strain, the titer of the first-stage serum may be found to be considerably lower, and then a diagnostic increase is observed. In other instances the titer may be high because the true onset was earlier than that recorded, and viral antibody has developed before secondary complications began. If results of this nature are obtained in the hemagglutination-inhibition reaction, the presence of nonspecific inhibitor should be suspected, and then the sera should be treated to eliminate that effect and retested.

The serologic procedure most commonly employed is that of hemagglutination-inhibition in which antibody content is measured by a specific capacity of serum to prevent agglutination of erythrocytes by the test virus (Hirst, 1942b). Chicken cells, human O cells, guinea pig cells are used most frequently, although those from other species may be employed in special circumstances The patient's sera should be tested against the different types of influenza virus unless the epidemic strain is available. Antibody rises of 4-fold or greater are obtained with homologous strains and frequently with closely related strains of the same type. Ordinarily, an increase to other types is not observed. With strains newly isolated in eggs the convalescent serum titers may be low, and the virus may be especially susceptible to normal inhibitors This creates difficulty in obtaining satisfactory readings with low dilutions of serum, and the impression is gained that no antibody rise is occurring After further egg passage or after mouse passage, their serologic behavior may be improved

quired antibody to Type A strains by previous exposure will ordinarily exhibit in convalescence a rise to other related strains in addition to that of immediate infection In fact, the convalescent titers to other strains may reach new levels well above those to the homologous strain, although the increment of increase to the latter is much higher These effects emphasize the joint relationships between strains and their influence as secondary stimuli to enhancement of previously acquired antibody. Their significance is seen in that the younger segments of the population behave more as immunologic virgins with relatively low convalescent titers limited to recently dominant antigens, while adults present a response which may be detected with varied strains, depending upon age and experience. The effect of previous experience may also be reflected to some extent in the response measured by complement-fixation test. However, when epidemic strains arise which are sharply different antigenically from those of recent years, the hemagglutination-inhibiting response may appear to be highly strain-specific

through much of the age range. Nevertheless, even in 1957 some cross-reactions with earlier strains have been observed in convalescence.

The complement-fixation test with soluble antigen is type specific, essentially unaffected by nonspecific inhibitors and may be conducted with antigen from any of a number of strains of the same type. Vaccination ordinarily induces limited complement-fixing antibody so that infection in vaccinated persons can be detected without interference from pre-existing high hemagglutinin inhibition titers to other strains. Using allantoic fluid as viral antigen, a greater degree of strain specificity may be encountered, but this is not usually a serious limitation. When using progressive dilutions of serum, a 4-fold or greater rise is significant. Good responses are also obtained with antigen prepared from infected mouse lungs.

The mouse protection test for neutralizing antibodies is comparatively precise. The titers obtained are roughly proportionate to those of the hemagglutination-inhibition test but numerically may be quite different. There is less strain specificity, and protective antibody may be demonstrated to strains which appear quite different in the agglutination test.

The clinical differentiation of influenza from other illnesses may depend upon the absence of characteristic features of those illnesses. The typical common cold is more an afebrile illness with profuse coryza and congestion of the upper respiratory tract predominating. Acute streptococcal pharyngitis exhibits the localized pharyngeal inflammation with exudate and leukocytosis. Coxsackie virus infections may present herpangina, pleurodynia or aseptic meningitis. Acute respiratory disease associated with adenovirus infection is difficult to differentiate, although the course may be longer, and in some outbreaks the frequency of conjunctivitis is a distinctive feature. In military populations the selective distribution of adenovirus illness among new recruits is different from influenza which commonly affects all groups. In the incipient stage, particularly, many other illnesses, such as psittacosis, Rift Valley fever, lymphocytic choriomeningitis, ECHO virus infections, bacterial pneumonia, or sinusitis may resemble influenza. However, adequate etiologic differentiation remains primarily a matter of laboratory investigation.

TREATMENT

There is no specific therapy for influenza. In the usual uncomplicated case of influenza, treatment is essentially palliative and symptomatic. The most important measure is the assurance of complete bed rest. It is better for the patient to remain at home without visitors than to be hospitalized where exposure to bacterial infections may be extensive. The room should be kept at a comfortable temperature; cold air aggravates coughing and irritates an inflamed respiratory tract. A simple diet with adequate fluids is well tolerated. Simple medications will relieve the myalgias; heavy sedation should be avoided. If cough is troublesome, cough syrups such as elixir of terpine hydrate with or without codeine are helpful. Codeine is useful for general relief as well, since it provides comfort without unduly obscuring the febrile course. Acetylsalicylic acid or similar antipyretics give great relief, but the perspiration which accompanies their effect may be disturbing. Substernal soreness may be relieved by use of hot-water bottle or electric pad. Bland gargles may relieve pharyngeal discomfort. Nose drops or inhalants are satisfactory for nasal congestion, but oily sprays should be avoided.

Sulfonamides and antibiotics do not affect the virus infection. However, there is a great tendency to use them under the guise of preventing complications. The council on Drugs of the American Medical Association has recently issued the following statement prepared by a Special Committee on Influenza (1957):

> Antibacterial compounds such as sulfonamides or antibiotics should not be generally used in the prophylaxis of bacterial infection in patients with influenza. The prime reason for this recommendation is to prevent the development of disease-producing strains of micro-organisms which would be resistant to sulfonamide or antibiotic therapy. The secondary reason is to obviate the development of reactions of sensitivity or of direct toxicity to antibiotics or sulfonamides. The possible exceptions to this injunction are (a) pregnant women, debilitated infants, and older individuals, (b) patients being treated for other bacterial infections with sulfonamides or antibiotics who develop influenza, and (c) patients

suffering from chronic, nonallergic respiratory tract disease.

All patients ill with influenza in whom it has been demonstrated that secondary bacterial infections have developed should be treated with a sulfonamide or antibiotic of choice. In general, the following recommendations can be made as to the choice of sulfonamides and antibiotics. (a) pneumococcic pneumonia: penicillin, broad-spectrum antibiotic, sulfonamide,

monia.

sulfonan

monia· broad-spectrum antibiotic, (d) micrococcic pneumonia· this will be a real problem because of the resistance of strains of these organisms to sulfonamides and antibiotics Careful testing of the sensitivity to the various antibiotics of micrococci isolated from patients ill with pneumonia should be done and the choice of the antibiotic made upon data garnered from these tests If the condition of the patient is so grave as to necessitate immediate therapy, massive intravenous doses of penicillin plus 1 Gm of streptomycin per day may be administered while the results of antibiotic sensitivity tests are being awaited

Chloramphenicol appears to have greater efficacy against *H influenzae* than many of the other compounds

Since in large scale epidemics medical attention may be limited, the patient or his attendants should be informed that if symptoms increase in severity, fever persists beyond 3 or 4 days, or other serious change, the physician be notified, he in turn should be alert to possible complications In the small number of fulminating cases emergency measures must be applied. Since they usually exhibit acute pulmonary edema, oxygen and carbon-dioxide exchange is reduced, and treatment should be directed to its relief. Sedation must be used with caution Patients with mitral stenosis, chronic pulmonary disease, and pregnant women appear to present special risks apart from the hazards of bacterial infection. In the presence of concomitant staphylococcal infection the use of adrenal cortical preparations may be considered.

Some use has been made of animal immune serum or human convalescent serum without very gratifying results However, Russian investigators have continued in the use of intranasal insufflation of serum for treatment, but the evidence of its effect is not convincing Vaccination has no place in treatment.

Patients should return to normal activity with care, particularly if this involves strenuous physical activity. Adults commonly experience weakness and slow return to full strength. In a proportion of cases mental depression and signs of neurasthenia may be very troublesome. This requires sympathetic but confident support by the physician.

EPIDEMIOLOGY

Because the clinical manifestations of influenza are not of themselves sufficiently unique to identify the individual case or small group of cases adequately, influenza has been predominantly an epidemiologic diagnosis The classic features of influenza are its occurrence in epidemics which arise abruptly and spread rapidly but irregularly over a region. The disease appears in small, focal outbreaks, in epidemic or pandemic form Outbreaks are most common in the period from early autumn to late spring but may begin or extend during the warm seasons. In an area the peak may be reached in 3 weeks, and the course essentially completed in another 3 to 4 weeks There is a high morbidity and low mortality, although the occurrence is usually reflected in an excess incidence and mortality from pneumonia and in an increase of total mortality built up from increased deaths of persons with chronic, debilitating disease Despite the absence of pathognomonic

abrupt onset with chills, aches, fever, prostration without prominent respiratory signs, and uncomplicated recovery beginning after 3 to 4 days of illness Influenza can be considered

viruses which may differ qualitatively and quantitatively but possess similar pathogenic properties Variations in severity and extent can be related to differences in the host population, in the primary causative agent and in environmental influences This concept of the epidemiology of influenza permits its consideration according to principles underlying the ebb and flow of other epidemic diseases of man transmitted by the respiratory route.

Morbidity

Incidences of 20 to 40 per cent have been noted repeatedly in general populations during extensive outbreaks. In isolated populations or in concentrated groups even higher attack rates may occur. Based on house-to-house surveys in one area, Collins (1944) reported a civilian attack rate of 15 per cent during the 1943-44 epidemic of influenza A. In certain military establishments the combined incidence of hospitalized and dispensary cases was 15 to 16 per cent, and in 1947 it was 8 per cent. In the 1957 pandemic extremely high rates existed in various countries, adequate data in the United States are not yet available. At carefully observed military posts rates as high as 10 per cent occurred, while on naval vessels rates of 50 to 60 per cent have been reported. In outbreaks of intervening years, however, rates of 2 to 5 per cent have been more frequent. Outbreaks of influenza B have also varied. A population survey of influenza B in early 1937 indicated an incidence as high as 30 to 40 per cent in some affected communities, while in 1954-55 in a closely observed population it was about 2 per cent. In addition to clinical disease, a high frequency of inapparent infection can be detected serologically.

Age Distribution

The age distribution of cases is best determined from specific surveys. These data emphasize that the highest incidence is usually at 5 to 9 years. There is a sharp reduction in the 15-to-24 age group followed by a rise between 25 and 34. Thereafter a downward trend follows to a further low in older ages (Collins, 1944, Francis 1953). A somewhat similar distribution was observed with influenza B in 1936 (Francis, 1937). On the basis of current data the 1957 pandemic exhibited an age incidence of this form also. Preliminary information from the U. S. National Health Survey (1958) has provided weekly rates of new bed cases in the United States of 28 per 1,000 at 0-5, 40 at 5-19, 16 between 20 and 64, and 9 in persons over 65 years of age.

Mortality

There is little information regarding fatalities from the viral disease alone. The ascribed mortality predominantly relates to pneumonia largely associated with bacterial invaders. The mortality rate is a resultant of attack rate and case fatality. In the majority of epidemics case fatality scarcely exceeds 1 per 10,000. However, it is estimated that in the autumn of 1918 the average case fatality in the affected population of Europe and North America was about 2 per cent (Jordan, 1927). In certain native or inexperienced populations mortality rates of 10 to 20 per cent were reported. Among Allied military forces in France in 1918 case fatalities of 6 to 7 per cent were recorded from influenza and pneumonia. Great variation occurred in different military installations in the United States with reported case fatalities from 2 to 10 per cent. It is apparent, then, that mortality varies with the extensiveness and the severity of the epidemic. The latter is influenced by the virulence of the virus and the frequency of bacterial complications. For instance, the influenza A of 1943-44 in the United States had the highest incidence since 1918, but the lowest recorded percentage of cases complicated by pneumonia, nevertheless, by virtue of the high incidence the resultant excess mortality was high (Collins, 1944). In 1957 again the mortality was low everywhere despite extremely high incidence. The age distributions of mortality and case fatality differ significantly from that of age incidence. Ordinarily, the age mortality curve from respiratory disease has a skewed U shape, proceeding from a high point in the first years of life to the lowest period at 15 to 25 years and increasing progressively thereafter to its highest point in old age. Influenza tends to displace this mortality curve upward with increased rates beginning at earlier ages. The lowest case fatality ordinarily occurs in the age period of highest influenza incidence, while it tends to become exaggerated in the period above 40 years where the incidence is decreasing. In 1918, however, the frequency of reported pneumonia was high at all ages, but strikingly the age group of 20 to 40 exhibited the highest incidence of complicating pneumonia with a resulting high case fatality which distorted the over-all age mortality curve to the form of a W. The pneumonia rates declined consistently after 40, although case fatality increased to the peak after 60. This deviation with high mortality in middle age has been said to indicate a different etiologic and epidemiologic entity. It may more reasonably be attributable to an exaggerated physiologic stress of pneumonia on males of this age, for it was distinctly less evident in females. The factors responsible for the increased case fatality of 1918 appear to differ from those responsible for influenza morbidity. The increased immunity of older ages to the vi-

rus infection made them less susceptible to pneumonia, but when they developed pneumonia their fatality rates were higher (Francis, 1953). Stuart-Harris (1953) has called attention to the increasing proportion in recent years of all deaths related to influenza which has been observed in persons over 55 years of age. The excess mortality from all causes which occurs during influenza epidemics also tend ... young ... other ... ion A recent review by Collins and Lehmann (1957) emphasizes the progressive and the steep decline in mortality from influenza and pneumonia since 1936-37 and the advent of effective therapeutic drugs. Moreover, the excess mortality in epidemic periods has also been declining from 44.4 per 100,000 in 1928-29, 18.4 in 1936-37, 14.4 in 1943-44 to 6.9 in 1953. From 1953 to 1957 essentially no excess mortality was detected.

Epidemic Spread

Procedures for the identification of influenza viruses have provided accurate means for mapping the development and the spread of recurrent outbreaks on a broad scale. Nevertheless, this information could be correlated only when information from active, regional laboratories was pooled. A series of detection centers was established for this purpose by the Commission on Influenza in 1942 and augmented by laboratories of American Armed Forces in various regions. The World Health Organization began in 1947 the development of a co-ordinated system which is now world-wide. Continuous observation has demonstrated that extensive outbreaks may be preceded for some months by small, apparently local, flurries caused by the same strain of virus. This was first noted for influenza A in 1943 (Hare et al., 1943; Francis, 1945). In 1945 scattered prevalences of influenza B were identified for 8 months in the United States, in the Pacific area and the Southern Hemisphere before the major peak in November of that year occurred in North America and Europe (Francis et al., 1946). In other years, a sampling of illness has commonly failed to reveal influenza until the beginning of a definite outbreak; however, these observations have usually involved only large metropolitan centers and few laboratories. It has not been uncommon to find that the strain in circulation during the winter months in the Southern Hemisphere then appears 6 months later during the cold season of the Northern Hemisphere or vice versa. Areas such as Puerto Rico and Hawaii with little seasonal variation appear to behave as crossroads. From July to September, 1940, influenza A was prevalent in the Southern Hemisphere, the West Indies and Hawaii; it reached the West Coast of North America and spread eastward during that winter (Francis, 1943). The A-prime strain (Cam) which was isolated in Australia in 1946 was found to be a forerunner of the initial A-prime dispersion in the Northern Hemisphere early in 1947; they were first recognized in Russia in 1949 (Smorodintsev and Zhdanov, 1957). Chu et al. (1950) described the northerly spread of an A-prime outbreak through Europe in 1949. The best studied example of antigenic uniformity in a pandemic distribution is that of 1957. Although variations in serologic reactivity were noted, antigenically the Asian strains were essentially identical wherever isolated. Early in 1957 influenza in the United States and other parts of the world was caused by A-prime strains, in the fall, Asian strains prevailed. However, successive waves in a region may be related to different types of virus. In the early months of 1940 influenza B was prevalent, but influenza A occurred in the autumn; influenza A may be prominent in one year and influenza B in the next. On the basis of limited experience it was suggested that influenza A had a 2- to 3-year cycle, while that of influenza B was 4 to 5 years, but this is far from regular. Since 1935 there have been 11 identified general prevalences of influenza A in the United States and 5 of influenza B (Table 28). The experience of other countries is similar, and there is reasonable agreement in the timing of the strain prevalences in different countries. Interestingly, the antigenic character of the strains identified in different parts of the world at a given time is much the same. This is particularly true when major prevalences occur. There are repeated indications that under certain circumstances strains of different character may be encountered in a given area as first noted in 1936 (Smith and Andrewes, 1938). Isaacs and Andrewes (1951) have described the experience in Great Britain in 1950-51 where they conclude that a confluence of somewhat different A-prime strains occurred, one derived from Scandinavia, while the other, which caused more severe disease in Liverpool, came up from the South. Scattered cases of influenza B have been noted interspersed with epidemics of influenza A; influenza C has been detected in

conjunction with outbreaks of influenza A or B. The outbreak of influenza D in Vladivostok occurred in company with influenza A (Gerngross, 1957). Double infections also occur. Therefore, mixed prevalence may be expected, although the tendency toward conformity in strains from a widespread epidemic is dominant despite demonstrable but limited individual variations

These observations indicate that the strains of virus are transmitted widely and readily with mutants of epidemic capacity dispersed in multiple foci until a sufficient concentration of infection builds up or environmental conditions, such as cold weather and increased crowding of the population, enhances opportunity for transmission These considerations are of importance in interpreting the source and the distribution of epidemics

Origin of Epidemics

No reservoir of human influenza virus has been demonstrated such as the lung worm indicated by the work of Shope (1941) for swine influenza virus in the United States As mentioned elsewhere, there are reports of recovery of strains corresponding to human virus from other animals (cf Host Range)

In the earlier literature repeated suggestions are made that major epidemics arose from endemic sources in Turkestan or Eastern Russia and extended to the West along the routes of travel (Jordan, 1927, p 74) Evidence indicates that while the initial source of the virus is not known, the severe pandemic strain of 1918 was primarily recognized in relation to the military areas of France. Thereafter spread was rapid and diffuse. Nevertheless, opinions that it was of Asian origin were commonly expressed There is not at present sufficient information to assume that a single localized focus or reservoir exists in which epidemic variants primarily arise The experiences of 1943 and 1947 influenza A and 1954-55 influenza B readily suggest that each of those variants arose in a different place Whatever the source, there is no doubt that spread is essentially a point-to-point phenomenon, and numerous small foci may be established before coalescence into a full-blown epidemic occurs

The spread of the 1957 epidemic provides striking illustrations of the mode of dissemination From the interior of China in late February and March the disease extended in early April among refugees in Hong Kong Extension to other Pacific areas was commonly and clearly related to specific imports by ship or plane American naval vessels touching [illegible] of [illegible] it [illegible] at [illegible] vessel off Newport, R I., was noted in May Then an outburst occurred in a student conference at Davis, Calif , members of that conference introduced it into other regions, including another conference in Grinnell, Iowa From that, secondary distributions occurred widely California representatives took the disease to an International Boy Scout

Jamboree, whence further scattered foci were established Other outbreaks were related to migrant laborers from the Southwest. In the meantime, the epidemic had spread, often in limited extent, to other areas radiating from the Asian focus so that by mid-June influenza had circled the globe It was notable that initial prevalences in many areas were seen in crowded populations or special groups in close quarters The peak of prevalence occurred in the last 2 weeks of October, and it is estimated that in the United States there were over 11 million new bed cases in each of those weeks (U. S National Health Survey, 1958). Thereafter, a progressive decline occurred, although scattered illness persists Were it not for the close attention and the rapid communication of information, this outbreak, too, could have given the impression of rising spontaneously in numerous parts of the world (Figs 109 and 110). However, the

of the virus by association but also demonstrates that a sufficient nucleus of infection is needed to induce major epidemics This is undoubtedly increased by a sizeable proportion of inapparent infections. Another effect of crowding is seen in the extremely high incidence in congested populations of the East, in the companies of ships and certain industrial groups This was further observed when students convened in schools and colleges in the early autumn, the disease began promptly and led to high incidence among them The impression was gained that it was frequently more marked when this represented a close mingling of students from many areas rather than merely local aggregations

One concept of the development of a pandemic is that it erupts simultaneously in many areas This implies that virus possessing essentially the same characteristics arises independently in many different areas—presumably because of a variation forced by immunity of the population It is difficult to accept this in view of the comparative antigenic uniformity of the strain in wide circulation It is more likely that the early distribution is unrecognized

The emergence of a new epidemic strain [illegible]

e

e

t

-

sources of the individual host in which it arises

and that of the surrounding population Its ability to disseminate is, then, determined by its infectious property, that is, its capacity to multiply in a new host to which it gains entrance. That capacity may be progressively enhanced, as is seen in the experimental adaptation of a strain to a new species so that the amount of inoculum required is decreased, the lag period is eliminated, more virus is produced, and severity of injury to the host may be increased. Thus, pathogenicity and dispersibility may be established and stabilized at a high level with passage through the human population Virulence or severity of injury may also become stabilized at a mild or severe level but is a variable independent of infectiousness, except as the virulent virus depends on other properties for its transmission Theoretically, as infectivity increases, virus may survive in more resistant hosts and adaptation of the strain to higher virulence may ensue. However, it is the common experience that when a strain becomes sufficiently well adapted by passage in a human population as to extend widely, its pattern of behavior is well established. In view of the high degree of mutability among influenza viruses, there must be countless variants of influenza virus which appear and promptly disappear because of lack of appropriate infectivity or opportunity to develop it.

Presuming that the mutant virus arises in a resistant host by reorganization of its antigenic components so that it can survive, the most favorable environment for its further propagation is the young portion of the population which will have had the least previous experience. Moreover, concentrated populations will heighten the chances of rapid passage One can believe that this can happen in a limited community but still lead to a dead end because there is no outlet to the wide world Unless some mode of maintenance besides continued transmission in man or other species is available, that strain is lost Or the virus may acquire ready infectivity but be stabilized at an immature nonpathogenic, avirulent state (Andrewes, 1950), behaving as an antigenic neutron, transmissible RNA, or an R form which can be induced subsequently to acquire more specific character. However, the evidence is clear that large epidemic prevalences are essentially limited to the distribution of a strain of matured virus which probably originated and became established initially in a limited area Occasional strains of local character or strains which have not completed their excursions in the popula-

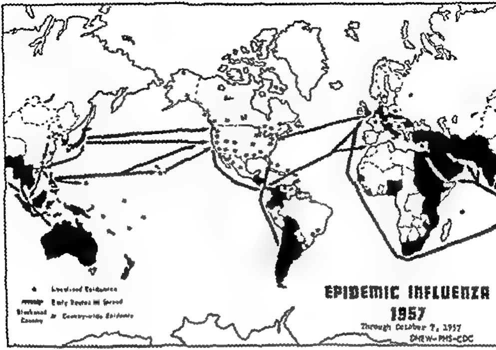

FIG 109 (U S Department of Health, Education, and Welfare, Public Health Service)

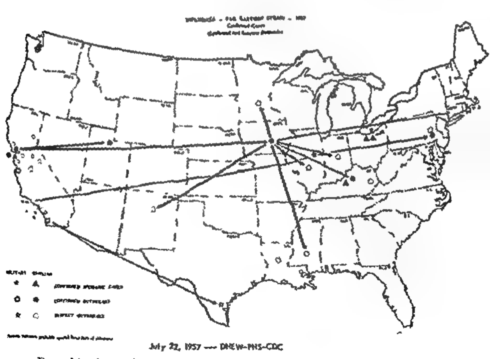

FIG 110 (U S Department of Health, Education, and Welfare, Public Health Service)

tion may well be encountered in a community That pandemic distribution is not a function of virulence and that virulence is not a requisite of sharp antigenic variation is well demonstrated in the experiences of 1947 and 1957 when marked deviations of the Type A strains were associated with pandemics of mild character Nevertheless, mild but world-wide distributions are commonly overlooked, and the term pandemic is used to denote a wide distribution of the more virulent agents. In reality it seems likely that most strains encountered in epidemic form achieve pandemic distribution

Immunity

The duration of immunity to influenza is not adequately determined, complicated as the problem is by multiple antigenic variants Shope (1931) has noted that adult hogs which have gone through one epidemic are not affected the next year, and the annual recurrences appear to be limited to the new offspring This may account for the antigenic uniformity of the swine influenza strains in America In mice, a durable immunity after infection is observed In ferrets, immunity wanes after a few months, but a modified resistance persists which prevents pulmonary involvement, although it may not prevent febrile illness and damage to the respiratory epithelium on reinoculation However, resistance can be made more effective by repeated respiratory exposures during the immune period. It is noteworthy that the repair of epithelium is markedly accelerated in the partially resistant animal and may be part of the defense mechanism

Experimental studies in man have shown that 4 months after a clinical illness induced by inhalation of Type-B influenza virus a third of the subjects exhibited illness again when resprayed with the same virus (Francis et al., 1944) Similar results were reported by Henle et al (1946) after influenza A Still other experiments by the Commission on Influenza (1943) obtained by second inhalation of Type-A virus after 2 months revealed firm resistance. Identified second bouts of naturally acquired influenza have been observed in children a year after an attack by a closely similar virus It is well recognized that adults, too, may develop influenza at

itation. Family studies have demonstrated repeatedly that those members affected in one epidemic are less likely to be involved by the next outbreak of the same type In fact, the impression from detailed histories of experiences indicates that the resistance may persist for extended periods There is no evidence of cross-immunity between influenza A and B

Epidemiologic studies have shown, however, that there is a relation between the level of circulating antibodies and resistance to either natural or induced infection Because influenza virus infection is an attack upon a superficial tissue which is essentially extravascular, the influence of circulating antibody in preventing injury to the respiratory epithelium is believed to result from the diffusion of these antibodies into the nasal secretions which at the portal of entry can combine with virus and prevent its pathologic action (Francis, 1942). They are increased after infection or after subcutaneous vaccination (Francis et al, 1943), reflecting at a lower level the enhanced titers in the blood Antibody developing after infection persists for

tected by customary procedures However, when they are re-exposed to the same or similar antigenic strains by infection or vaccination, they exhibit an accelerated and broadened antibody response to viruses of that type (Quilligan et al, 1948) Persons of different ages present different patterns of antibody, reflecting the nature of the strains to which they have been exposed during their lifetimes The sera of children contain antibodies to the dominant antigens of viruses with which they have recently been infected Since these are primary experiences, there is limited crossing with secondary antigens The older age-groups have a broader serologic activity It reflects the reaction not only to more

antibodies are first found in a population is determined by the history of influenza prevalence in the community. The frequency rises rapidly so that by 10 years of age the majority of individuals will possess antibody to recent strains part of which must certainly be antibody acquired from secondary antigens of related strains When pools of sera representing the age span of a population are tested against different strains of virus whose periods

of prevalence are known, it is seen that the highest titer exhibited by an age-group is to the strains which were circulating at the time of that group's childhood This has led to formulation of "the doctrine of original antigenic sin" which says that the antibody which characterizes an age-group through life is that to the dominant antigen of the virus present in the initial infection of life, as repeated stimuli are received from exposures to related strains this primary antibody is successively enhanced, presumably by common lesser antigens, so that it maintains the highest titer at all times Nevertheless, there is *a progressive broadening of antibody coverage* to the multiple antigens of varied strains of influenza virus, and the response to dominant antigens of later infecting strains is dampened by the composite antibody which has developed.

Epidemic Recurrences

The young segment of the population is typified by antibody to A-prime strains which appeared in *1947*, persons of *18* to *30* by antibody to typical A strains (PR8), persons of 30 to 60 by the swine strain (Francis et al, 1953, Hennessy et al, 1955, Davenport and Hennessy, 1956, Davenport and Hennessy, 1957) It was first demonstrated by Mulder (1957, 1958) and repeatedly confirmed in other countries that persons of 70 to 80 years of age may possess antibodies to the new 1957 Asian strains This new strain will also dominate the antibody pattern of present-day children (Mulder, 1958) These antibody patterns correspond strikingly to what is known of strain prevalences (Fig 111). The same patterns have been noted in the sera of populations in the United States, England, Japan and Czechoslovakia (Davenport et al, 1955, Davenport and Hennessy, 1958, Blaskovic and Rathova, 1956) Since 1935 when studies of the age-distribution of antibodies to swine, PR8 and WS strains were first made, the age-distribution of antibodies in the population to those strains has shifted chronologically in keeping with the passage of time (*Francis et al, 1953*) These data emphasize

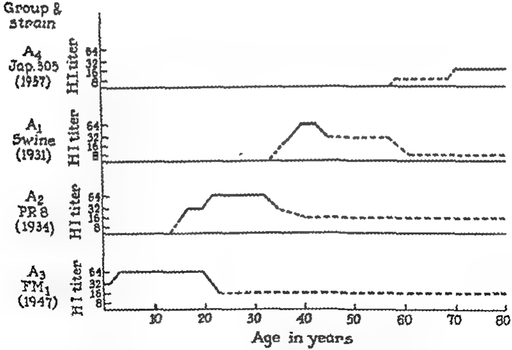

FIG 111 Age distribution of antibodies in the general population to groups of Type A *influenza virus* (Redrawn after Davenport, F M, Hennessey, A V., and Francis, T, Jr, 1953, Epidemiologic and immunologic significance of age distribution of antibody to antigenic variants of influenza virus, J Exper. Med *98*, 641-656)

the probability that a virus antigenically similar to swine influenza virus was associated with the 1918 epidemic in man, and Mulder (1957, 1958) has suggested from the time relation of antibody to Asian strains that this virus may be the agent prevalent in the pandemic of 1889-90. Moreover, it has been well demonstrated that the characteristic antibody of an age group is enhanced by vaccination with any strains of the same type, and further that a primary conditioning to a given strain can be established by vaccination with that strain as well as by infection Through these studies it has become clear that the younger segments of the population are lacking in antibody to strains which were prevalent as recently as 20 to 30 years ago The sharp strain-specific character of antibody in childhood is reflected in the uniformly high incidence at that age in succeeding epidemics caused by closely related strains; the reduced incidence above 40 or so reflects the accumulated broader, less strain-specific antibody, the immune behavior of persons in the middle range can be expected to be intermediate in character determined by the multiplicity of their experiences in relation to the antigenic character of the epidemic strain.

On the basis of this evidence variations in age incidence and epidemic recurrences can

tion Under these conditions, the hypothesis that virus variation occurs within finite boundaries also postulates that in the accession or the recession of antigens these areas of deficiency invite a back mutation, bringing into prominence again epidemic strains with major antigens characteristic of earlier strains This has now been clearly demonstrated by the presence of antibody to the 1957 Asian strains in the older segment of the present population A cycle has apparently been completed. The significance of immunologic experience accumulated earlier with antigens of apparently new strains is also reflected in the progressive decrease of incidence in persons over 30 years of age in the 1957 and in other experiences The fact that some normal children possess antibodies to the Asian 1957 strains points to the existence of that antigen in other recent strains The development of antibody to swine virus in young children infected with A-prime strains indicates that the primary swine antigen is also still prevalent New epidemics may thus represent strains with dominant antigenic characteristics differing from those of immediately preceding years but similar to major antigens of earlier strains or to secondary antigens encountered in a variety of strains Therefore, cyclic recurrences of epidemics can be expected in which the antigenic dominants of older strains, taking advantage of the increas-

is opening widely On the basis of present knowledge it seems more likely that this will constitute another rearrangement of existing antigens rather than the return of the same strain which has remained intact for an interval of many years If, however, a sustained reservoir should be demonstrated, as Mulder suggests (1958), a recurrence of the intact strain could occur The periodicity of such events should be quite irregular, governed by mutational chance and population characteristics rather than an inherent cyclic germination of the strain itself

Influenza B has been encountered less commonly in extensive, abrupt epidemics than influenza A, and there tends to be a longer interval between outbreaks Low-grade endemic and sporadic distribution seems to be rather constant The relative incidence in children is higher than in adults In one instance Magill (1945) described a high incidence of clinical illness in prisoners-of-war groups, while inapparent infection was more prominent among

genicity on a more continuous scale could play an important role in the lesser frequency of epidemics of influenza B. Cross relationships between Type-B strains appear to be more extensive, so that immunity is of greater duration Moreover, effective vaccination of human subjects against influenza B has been less affected by strain differences

Influenza C has been shown by antibody studies to be widely distributed as an infection in the population, and the recognized clinical manifestations are those of mild upper respiratory infection Up to the present only small localized prevalences and scattered cases have been specifically identified in various parts of the world

As noted elsewhere, the characteristics of influenza D have not been thoroughly mapped nor is its relationship to man and other animals—mice and swine—satisfactorily established It does not appear to belong to the

Newcastle disease group. The recovery of strains from human epidemics in Russia and serologic evidence indicate that it is prevalent as an infection. In Glasgow, Grist et al (1957) reported a new case in a 75-year-old man. In the United States in 1954 the highest frequency of antibodies was noted in the age groups of 10 to 20 years, while infants and young children had little or none (Jensen et al, 1955). In Japan the frequency of antibody varied in different districts, and this is reported also in Russia (Kuroya et al., 1953, Gorbunova, et al., 1957). Chanock et al (1958) have recently reported isolation in the United States of strains which appear to be Type II. They were recovered from children with croup. They have recovered still another virus from epidemic respiratory disease of children, which they suggest tentatively may be influenza E.

CONTROL MEASURES

Owing to the short incubation period, the abrupt onset and the high infectiousness, limitation of the spread of influenza by population control measures such as isolation and quarantine scarcely seems to be applicable. The 1918 experience in Australia, for instance, has been considered an indication that strict maritime quarantine might be effective in preventing introduction into a new community (Cumpston, 1919). In 1957 numerous incidences occurred which clearly related the introduction of influenza into unaffected countries by passengers from airplanes or by passengers or crews of infected ships. In military units the tendency to ignore interchange or transfer of men limits any possible effectiveness by such means. Nevertheless, it may be that if a severe epidemic were to be known to be approaching and a rigid quarantine were instituted, some delay could be obtained. These procedures have always encountered economic obstacles when epidemics are so commonly mild, they are also difficult to enforce administratively. It is quite clear, nevertheless, that arrangements which reduce crowding can have an influence on the rate of spread and on incidence in a given population. Here again the experience of 1957 is of interest in that the majority of the initial foci of disease appeared in groups gathered in close proximity.

Attention has been given to application of air-sterilization in such a way as to create a barrier to transmission of influenza virus. In crowded groups or in close quarters where air may be heavily contaminated by affected persons this, theoretically, should have some influence. Up to the present time, however, the use of various aerosols or ultraviolet light has not proved to be an effective means of control.

The greatest attention has been given to the development and the application of prophylactic vaccination. In this the Commission on Influenza of the Armed Forces Epidemiological Board has played a leading part. Their well-controlled investigations have continued over a period of 15 years, employing various preparations of vaccine. They have involved periods of high incidence and low incidence in such a way as to test the significance of certain vaccines in the face of outbreaks associated with strains of different degree of antigenic variation.

The approach to prevention of influenza by vaccination is based on the observations that recovery from infection is accompanied by antibody development and resistance, that in experimental animals antibody production and immunity can be induced by pararespiratory injection of active or inactive virus and that circulating antibody levels comparable with those observed in convalescence can be obtained in man by vaccination, presumably reflecting an accompanying immunity. Moreover, it has been shown that vaccination enhances the neutralizing capacity of nasal secretions in man, thus providing increased protection to the susceptible cells of the respiratory mucosa. In ferrets and mice vaccination has been shown to prevent the severe virus pneumonia produced by well-adapted strains of virus, even though susceptibility to the primary epithelial injury may remain. The effectiveness of vaccination has been clearly shown to bear a relation to amount of virus antigen administered. Recovery of swine from infection with influenza virus alone protects against combined infection with virus and bacterium, showing that the virus is the essential factor in providing immunity.

A number of early studies with active or inactive virus from various sources demonstrated the antigenic influence of vaccine, but the results in field prophylaxis were incon-

sistent owing partly, at least, to low incidence of disease, inconstant potency of vaccine and strain variation. In 1943 the now classic study with alternate placebo controls, conducted by the Commission on Influenza in ASTP units, clearly showed that subcutaneous vaccination with concentrated inactivated virus from chick allantoic fluid would prevent epidemic influenza A with an effectiveness of about 75 per cent The incidence of disease in the vaccinated was inversely related to the level of circulating antibody to the epidemic strain; this observation has been substantiated repeatedly. It was noted that the effect of vaccine became evident in 7 to 10 days after its administration when antibodies are accumulating. In some of the study units streptococcal infections were prevalent at the time influenza appeared without creating significant complications. Other reports indicated that influenza was significantly reduced in institutional populations vaccinated a year earlier

In 1945 the same vaccine which contained both Type A and Type B virus antigens was shown to be effective in prevention of epidemic influenza B At the University of Michigan and at Yale University the incidence of the disease in totally vaccinated Army and unvaccinated Navy units was compared Rates in the vaccinated were 1.1 and 0 5 per cent; in the unvaccinated 10 and 12.5 per cent, respectively, yielding an estimated effectiveness of 90 per cent or more

The foregoing results compiled by different observers were conclusive evidence that vaccination can be a practical, effective prophylactic measure The problem of strain variation was still to be reckoned with, however, and in 1947 vaccine of the same composition was found to be ineffective in an epidemic caused by the newly emergent A-prime strains The significance of strain variation in relation to immunity was thus convincingly demonstrated. This information has been extensively reviewed (Francis, 1950; 1954).

Since that time studies have continued with varied formulae of monovalent and polyvalent vaccines. The antigenic advantages of vaccines prepared with mineral oil adjuvants have been demonstrated, and limited observations of their prophylactic effect have been made (Philip et al, 1954; Boemi et al, 1955, Davenport et al, 1956). Shifts in antigenic character of Type-B strains have been evaluated; even though succeeding strains were serologically divergent, vaccination with the Lee strain of 1940 was found to give cross-protection against the later variants of 1945 and 1952. In early 1955, however, adjuvant vaccine with the Lee strain induced poor antibody response and low protection against the prevalent strain of Type B, demonstrating also significant antigenic shift in this type Table 29 summarizes results of the series of evaluations of vaccine conducted from 1943 to the present by the Commission on Influenza.

In many of these years the incidence of influenza in the study populations was low, so that excessive effort was required to separate influenza from concurrent disease of other nature It is particularly true in the studies among recruit populations in which adenovirus infections are commonly high

It should again be noted that while some reservations have been expressed [redacted] to whether influenza in vaccinated persons is adequately demonstrable by serologic procedures, a rise in titer to the homologous virus is ordinarily seen in convalescent serum with the hemagglutination-inhibition test and with the complement-fixation test as well Antibody rises have been readily observed in vaccinated persons subjected to experimental infection and in persons or animals undergoing a second experience with the same virus

The experience of 1957 was extremely informative in many ways The intensive collaborative efforts to provide vaccine with the Asian strains in the United States in the face of the oncoming epidemic was a remarkable accomplishment. Material for early initiation of vaccine studies was obtained in 2 months, and preliminary results were promptly obtained showing an effect of 40 to 75 per cent protection, depending upon the potency of the preparation (Commission on Influenza, 1957) It seems clear that older strains would not have provided high protection singly, but there are suggestions that polyvalent vaccine of earlier Type-A strains had a distinct though heterologous effect It is noteworthy that in the period of August to December

TABLE 29 SUMMARY OF VACCINE EXPERIMENTS CONDUCTED BY THE COMMISSION ON INFLUENZA

Year	Prevailing Type	Concentration of Vaccine	No Vaccinated	No Cases	Rate	No Controls	No of Cases	Rate	Protection Ratio

over 50 million doses of vaccine were distributed Priorities recommended under emergency conditions are important to review Among the first are the military defense forces, the medical and health personnel, those responsible for maintenance of community facilities and needs, essential industry, and persons of special susceptibility, such as those with chronic cardiac or other debilitating conditions, and pregnant mothers (Health Officers' Meeting on Asian Influenza)

The epidemic of 1947 which gave little warning and that of 1957 which was steadily traced bring into consideration two differing views of the outlook toward vaccination The one which has been a consistent perspective in the Commission studies is to seek an aggregation of the varied antigenic components representative of Type-A virus, for example, into a vaccine which will then encompass the range of variation and induce a broad antibody response to an extensive variety of strains The promise of this plan is bolstered by antigenic analysis of strains, by the age distribution of antibodies in the human population and by the fact that antibodies to newly recognized variants may be found in human serum before the variants appear epidemically (cf Epidemiology) This hypothesis also provides a hopeful basis, supported by immunologic and epidemiologic evidence, upon which to establish a well-rounded effective resistance by vaccination The group-character of convalescent antibody further points up strain interrelationships An alternate view, which seems scarcely consistent with present knowledge, is that new strains develop progressively with the appearance of

completely new dominant antigens unrelated to those of earlier times. The outlook according to this theme is that of finding the new strain and proceeding by emergency headlong procedures to provide vaccine against them in the face of the epidemic. If this is accepted, the outlook for vaccination is dark unless new methods and principles can be established. *It must be remembered that 25 years of acquaintance with influenza virus is but a short time in its history* Nevertheless, increasing evidence is developing to relate supposedly new variants, such as 1957 Asian strains, with preceding prevalences that have occurred within the life span of the present population.

Evidence has steadily accumulated to indicate that in the younger segments of the population which have had little or no experience with a given family of virus, more than one dose of vaccine at intervals of 6 weeks or more is desirable A single dose of high concentration has value for initial stimulation, but its practicality is limited by the increasing pharmacologic toxicity of increased virus content. This difficulty can be largely circumvented by giving multiple small doses at short intervals for the initial course Even with large concentrations of virus, multiple doses are needed for young inexperienced children In children or adults with some antecedent antibody to a strain, a single large dose of vaccine may produce a prompt development of high levels of homologous antibody and, simultaneously, antibody is enhanced to related strains encountered earlier (Quilligan et al , 1948, Davenport and Hennessy, 1957) Moreover, previous vaccination with related antigens may prepare the subject for increased response to vaccine containing a newly emerging strain Primary vaccination with monovalent vaccine of a new strain may condition the antibody production in such a way that antibody to it and other strains may be increased by a booster dose of a polyvalent preparation Consideration of the vaccination schedule and vaccine composition will undoubtedly add breadth and effectiveness to vaccination against influenza

Reactions to purified influenza virus vaccine are a function of virus content (Salk, *1948; Quilligan et al., 1948). In adults these* are primarily the localized foreign protein reaction with soreness, redness, swelling of mild character and limited duration similar to those observed *with typhoid vaccine. In children*, constitutional effects with considerable fever of 24 hours' duration may be seen with a full-scale dose. A certain proportion of adults (3 to 4%) may react similarly When increased numbers of severe local and constitutional *reactions are observed in adults*, other causes than vaccine per se should be considered, pyrogenic bacterial bodies contaminating the vaccine, excessive content of virus or extraneous protein. The vaccine ordinarily should not contain egg albumin; allantoic fluid itself is of low antigenic power; chicken tissue is not present in the material Nevertheless, severe anaphylacticlike reactions have been observed in persons with known natural sensitization to feathers, eggs, etc. They should not be injected with a full dose of vaccine from egg fluid It should be given in graded doses or omitted Repeated inoculations of vaccine have not been observed to cause sensitization White mineral oil adjuvant vaccines given intramuscularly elicit little local reaction and no systemic reaction even in children given an adult dose Preparations emulsified with Arlacel A in Drakeol 6 made for the Commission on Influenza have been used in large numbers of persons To date, a cyst has practically never been encountered, except with one experimental preparation which contained an impure emulsifying agent. No neurologic difficulties occur with such preparations There is evidence that subcutaneous inoculation may be more irritating locally. These vaccines offer much promise, but they have had only limited evaluation. However, serologic evidence clearly demonstrates that smaller amounts of virus in adjuvant produce more extended and higher antibody levels than aqueous vaccine preparation

From the first experiments with pararespiratory vaccines *indications have been* that reasonable antibody responses can be obtained with intracutaneous as well as subcutaneous or intramuscular inoculation (Francis and Magill, 1937) Much of present procedure has been based on military preference *Intracutaneous injections may* be multiple and repetitive It should be possible to obtain

adequate immunization by this route with attention to proper combinations of initial dose and intervals. Results are generally consistent in showing that a single 0.1 cc. intracutaneously is a less effective stimulus than 1.0 cc. subcutaneously. In children this defect is even more important because of their lack of previous conditioning experience. There are no reports of adequate field trials of protective effect of intracutaneous vaccine but they may be forthcoming from 1957 studies.

On the basis of experimental evidence vaccination should be of even greater effectiveness in preventing viral pneumonia injury than in preventing mild respiratory illness. Because of the comparative mildness of usual epidemics, there is little information regarding this feature. Pneumonia among vaccinated members of study populations has been very uncommon, and the deaths reported from the 1957 experience in the United States have been essentially limited to unvaccinated persons.

The duration of effective resistance resulting from single vaccination is not known nor is it adequately known after natural infection. Undoubtedly, the composition of vaccine and its potency are important factors. Mention has been made of protective effect apparently persisting for a year to significant degree. After a single moderate dose, antibody levels tend to decline by about one third in 3 or 4 months and to about one half the peak level in a year, at that time titers remain well above those in the rest of the general population (Salk et al., 1945). In children titers decline to very low levels more rapidly, but this depends upon the levels achieved after vaccination, that the conditioning effect remains can be demonstrated by revaccination. In one study cases among vaccinated children were seen to develop in those whose antibody had fallen extensively in the 2 months between vaccination and exposure. In certain experimental studies it was observed that 32 per cent of persons vaccinated 4½ months earlier exhibited clinical illness when subjected to Type A virus by inhalation, while 16 per cent of those vaccinated 2 weeks prior to testing had signs of illness but none with fever greater than 100° F. Fifty per cent of controls had characteristic illness. Vaccination against Type B apparently provided firmer resistance, 41 per cent of controls had illness, but only 10 per cent of vaccinated, and none with fever above 100° F., those vaccinated 4½ months earlier were as resistant as the groups vaccinated either 4 weeks before challenge or both times. It seems probable that increased use of multiple doses will have a valuable effect in lengthening durable immunity (cf. reviews, Francis, 1950, 1954).

The approach to immunization by modified respiratory infection with live attenuated virus has had steady consideration. It has certain theoretical advantages in that the natural route of infection is employed, the antigenic dose is increased by virus multiplication, and what influence the cellular reaction may provide is presumably obtained. In this country, studies with experimental infection suggested that as good or better protection was obtained after subcutaneous vaccination than after intranasal spray eliciting clinical illness. Live virus vaccination has been studied most extensively by Soviet investigators. The epidemiologic experiments conducted from 1938 to 1954 in different towns indicated the lowering by 1.5 to 3 times the incidence of influenza among persons vaccinated with live vaccine (Smorodintsev and Zhdanov, 1957). A study was begun in December 1953, at the onset of an epidemic of influenza A-prime involving about 15,000 workers in a cotton factory (Unanov, 1957). A live polyvalent vaccine containing strains of Types A, A-prime and B was used. A clinical incidence of 8.8 per cent was observed in the vaccinated and 44.2 per cent in the unvaccinated during the sharp epidemic period. In November, 1954, a study in 16,000 of this same population was undertaken with polyvalent vaccine of the same composition. An epidemic of influenza B began early in December and reached a sharp maximum in the latter half of January. Two per cent developed mild illness of short duration with fever, headache and respiratory catarrh from the administration of vaccine. Four groups were observed with clinical recording of illness during the epidemic prevalence which, according to serologic tests, was not more than 50 per cent influenza. The results reported are as follows

Groups	No	Cases of Influenza and Catarrh		Complications No
		No	Per Cent	
Vaccinated in 1954	6056	583	9.6	6
Vaccinated in 1953 & 1954	3931	476	12 2	5
	9987	1059	10 6	11
Vaccinated in 1953	1901	537	28.2	32
Unvaccinated	4972	1769	35.4	4
	6873	2306	33 6	36

Two vaccinations at a year's interval had no added effect, while vaccination in the preceding year had no demonstrable influence The maximum effect of 3 8-fold reduction occurred during the major epidemic period Serologic studies indicated 72 per cent of tested cases were influenza B; antibody rises to Type A were noted in 7 8 per cent and to A-prime in 10 5 per cent Data of this nature are not consistent, because effects from 1.5 to 5 times are reported from different studies Smorodintsev and Zhdanov (1957) reviewing the problem state that poor effects were obtained with the vaccine in 1955 because the epidemic Type B strains differed, as in the United States experience, poor results were also obtained when A-prime strains appeared in 1949. Observations of this nature would not be in keeping with the concept of interference protection. These authors present an excellent review of the problems involved in production of a satisfactory live virus vaccine on a large scale; they comment especially on the unsatisfactory results related to irregularities in desiccation, in infectious potency of strains, and in lack of quality control Strains for use are best adapted by passage in human susceptibles or in cultures of human embryonic lung They are still too virulent for children below 7 or 8 years Apparently, multiple strains must be considered to cover the antigenic range. Emphasis is given to the need for extensive inhalation to obtain consistent antibody production. The effect is apparently immunologic rather than interference, since infection with antigenically deviant strains is not prevented, and the effect begins in 7 to 10 days when antibodies appear. Its duration is obviously short. In fact, the selection of strains and other problems appear to create problems somewhat more complex than for inactive vaccine. In the autumn of 1957, 10 million doses of fourth egg passage virus of little attenuation were prepared. In this country much more inactivated virus vaccine was produced

Other studies have emphasized the disadvantages of too much attenuation Under these conditions, antibody response in adults is very uncertain In children, however, old strains may be effective without significant injury, although the Russian observers state that even these may cause marked clinical disturbance in young children.

One possibility, inadequately explored, is the intranasal spray of purified inactive virus Antibody response may be obtained, but a greater effect is obtained with smaller amounts of inactive virus subcutaneously (Quilligan and Francis, 1947).

Prophylaxis by means of intranasal spray of immune serum has been recommended by Smorodintseff, especially In one study he and associates reported a reduction in incidence of influenza under epidemic conditions from 82 per 1,000 in controls to 8 per 1,000 in the treated group by spraying with 2 0 cc of immune horse serum (Smorodintsev et al, 1940). This of itself constitutes a risk in sensitization. It has also been employed in treatment by the Russian investigators In extensive studies conducted by the Commission on Influenza with large individual inhalations of sprayed human convalescent serum and induced infection, no evidence of protection or therapeutic effect was observed

At present no effective prophylactic drug has been demonstrated, although there are numerous suggestions of preventive chemicals under experimental conditions in eggs, cultures, or mice. The use of bacterial vaccines as possible preventives of complications has not been seriously explored

Smallpox, Cowpox and Vaccinia

INTRODUCTION

Smallpox has been recognized as a disease entity for many centuries. Because of its striking clinical picture of severe illness associated with a pustular eruption, its occurrence in epidemics with high mortality and the dread which it has engendered in populations exposed to its ravages, the records of its incidence over the past few hundred years are more nearly complete than in the case of any other infectious disease. Although smallpox is not as widespread as it was a hundred years ago, there are still areas in the world where the infection is endemic, and constant vigilance is necessary for its control. In the present century a milder form of smallpox, with a very low mortality, has become common in Africa, Western Europe and America although such a type was recorded in England in the 18th century (Creighton, 1894). For this relatively benign disease the names "variola minor" or "alastrim" are used. It is clinically and epidemiologically distinct from the more severe form known as "variola major" or "classic smallpox."

Smallpox was the first disease for which prophylaxis by active immunization was widely practiced. In the 18th century this was done by the inoculation of smallpox (variolation). As a consequence of Jenner's paper, published in 1798, variolation was superseded by the inoculation of cowpox, a relatively mild infection of cows which occasionally affected farm workers. For many years the inoculation of cowpox or vaccination was carried on by arm-to-arm passage, and occasionally fresh strains were introduced from infected cows, so that as early as 1868 Ballard records that it was uncertain whence vaccine lymphs in current use were derived. For more than 60 years the virus strains used in vaccine lymph establishments throughout the world have been passed by dermal inoculation in calves, sheep or rabbits. During this time some strains at least have altered in certain minor characteristics so that they now differ from virus strains recently isolated from natural cowpox infections. These vaccinia strains have been the subject of extensive laboratory study, and to avoid confusion the strains recently isolated from cowpox will be referred to in this chapter as cowpox virus. Tentative approval has recently been given to the following names for the viruses under consideration: *Poxvirus variolae* (smallpox), *Poxvirus bovis* (cowpox) and *Poxvirus officinale* (vaccinia).

SMALLPOX

(SYNONYMS: Variola, *petite vérole*, *Blattern*)

HISTORY

It is generally stated that smallpox was prevalent in India and China before the Christian era but its first appearance in epidemic form further west was apparently in Arabia in the 6th century, possibly brought there from Africa by an Abyssinian Army. The

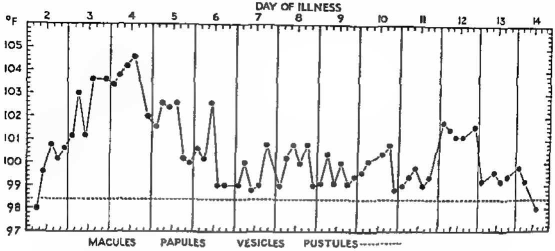

FIG 112. Chart from a fatal case of smallpox in an unvaccinated adult-death on 14th day of illness

disease was described by Rhazes in the 10th century, in the introduction to his work, translated from Arabic by Greenhill and printed in 1848, Rhazes states that the disease was described by Galen in the 2nd century Dissemination of smallpox from Asia to Europe and North Africa was associated with the invasion of these continents by the Saracens According to Creighton, the first clear account of smallpox in Britain appears early in the 16th century At this time also the disease was common among African natives brought by slave ships to the West Indies, and subsequently the disease took terrible toll among the Mexicans. In England smallpox was most deadly as an endemic

mortality in some years was approximately one sixth of the birth rate Over 90 per cent of the cases occurred in children under 10 years of age and in Chester from 1772 to 1777 one third of all deaths in this age group was caused by smallpox (Haygarth, 1793). In America where epidemics occurred at infrequent intervals the disease affected persons of all ages In Boston, Mass, there was no serious epidemic of smallpox between 1730 and 1752 In the latter year over one third of the population suffered from it, and all ages were attacked (Creighton, 1894). The endemic prevalence in Britain may have been maintained in part by the practice of variolation which was widespread in the second half of the 18th century Variolation was finally suppressed in England by Act of Parliament in 1840

The inoculation of smallpox introduced in England in 1721 did not immediately become popular, for the practice was not without risk to the patient The inoculation of smallpox matter by incision or puncture of the skin usually produced a local lesion with fever commencing on the 7th or the 8th day and a general eruption on the 9th or the 10th While this inoculated smallpox had a shorter incubation period and was generally milder than the naturally acquired disease, this was not always so In the first 8 years of the practice of variolation in England 17 persons of 897 inoculated were believed to have died from the subsequent disease (Woodville, 1796). Therefore, the practice fell into disfavor, but interest was revived following its successful use in Charlestown, S C, in 1738 There the practice was introduced of using matter from inoculated persons for further inoculation, and this modification was introduced into England, where inoculation was again taken up Most Western European countries did not adopt variolation until after 1750. With more careful selection of the material for inoculation and better care of the patient there was less risk associated with the practice than in the years immediately after its introduction However, even up to the time of Jenner's publication in 1798, the death rate from inoculated smallpox was reported to be about 1:200 to 1:500, at this period the mortality from naturally acquired smallpox was 10 to 20 per cent. It was under-

FIG 113 Pustular eruption of smallpox in an unvaccinated child

stood as early as 1722 that the inoculated disease was contagious, but not until many years later was the practice advocated, and in some instances followed, of inoculating whole communities at one time and isolating from the inoculated those who had not had the smallpox

In the 19th century the incidence of smallpox declined in Western countries and, except in such epidemic years as 1871 and 1872, became less important than scarlet fever and measles as a cause of death in childhood

In the 20th century variola major has maintained its lethal qualities in those areas of the world where it is endemic for example in 1950 there were recorded in India 157,322 cases with 41,092 deaths (Murray, 1951) On the other hand, the mortality from variola minor has been low Between 1920 and 1930, years of high incidence of variola minor in the United States and Britain, the mortality was less than 1 per cent

Clinical Picture

Little has been added by later writers to Rickett's classic description of the clinical aspects of smallpox (Ricketts and Byles, 1908), the following brief account conforms with his teaching, and the remarks on alastrim are largely based on the analysis of over 13,000 cases seen by Marsden between 1928 and 1934 (Marsden, 1948).

The incubation period generally lasts for 12 days The clinical illness begins with an initial toxemic phase which lasts for 4 to 6 days and is characterized by fever, constitutional symptoms and prostration There is usually severe headache, backache, pains in the limbs and sometimes vomiting In a proportion of cases a toxemic or prodromal rash with a predilection for the groins, the axillae and the flanks is seen, in milder cases this may be erythematous or in more severe cases petechial, and in the worst cases petechial hemorrhages may be present over much of the body surface On the third or fourth day the focal rash occurs and within a day or two thereafter the temperature falls near to normal, and the patient feels much better The focal rash usually appears first on the buccal and the pharyngeal mucosa, the face or the forearms and the hands and then spreads to the trunk and the lower limbs, so that for the first few days of the eruption the lesions on the face and the arms may be a day in advance of those on the legs In the typical case, however, the lesions in any one area are all at the same stage of development The macular rash quickly becomes papular, and within 2 or 3 days the papules have developed into vesicles, this stage is quickly followed by pustulation After about 8 or 9 days from the appearance of the focal rash crusting begins and is usually complete in 14 to 16 days from the onset of the illness By the end of 3 weeks most of the crusts have separated with the exception of those embedded in the palms of the hands and the soles of the feet The eruption is usually most profuse on the face, which may be swollen and edematous, and on forearms and hands The trunk generally shows more pocks on the upper part of

the back than on the chest Lesions are still less on the abdomen, while the groins and the axillae may be relatively free. More lesions are seen on the feet and the ankles and below the knee than on the thighs Except when the eruption is sparse lesions are to be found on the palms of the hands and the soles of the feet There is in all except the mildest cases some recurrence of fever associated with the stage of pustulation, but in cases which recover the temperature becomes normal as the lesions begin to dry up

In the most severe cases of smallpox the patient may die within the first week, even before the focal rash appears, for in some of these the focal rash is delayed The patient is extremely toxemic, and from the second or the third day hemorrhages occur in the skin, and there may be bleeding into the conjunctiva and from the mouth, the nose, the vagina and the bowel—*purpura variolosa* Hemorrhages may appear after the eruption in some toxic cases The extravasations of blood are situated in the corium below the epidermal lesions which appear hemorrhagic, but in addition hemorrhages may occur between the pustules—*variola pustulosa hemorrhagica* The severity of the illness in the eruptive phase parallels the extent of the skin eruption

Where the eruption is confluent on the face and the arms the vesicles may feel soft and show marked umbilication, this is especially so in the type of case which Dixon classifies as malignant confluent (Dixon, 1948) In modified cases with a discrete rash the elements are round, raised and tense, and depression of the center only appears, if at all, as the lesions are drying up In the mildest type of clinical infection the usual initial illness may not be followed by any focal eruption—*variola sine eruptione.* In vaccinated contacts a febrile illness without an eruption may be associated with radiologic evidence of pulmonary involvement The variolous nature of some of these febrile illnesses without eruption in smallpox contacts can be established by modern laboratory methods.

In cases modified by vaccination the prodromal illness may be severe. The rash may be scanty, or it may be profuse but superficial and evolving rapidly. These modified cases of variola major may be indistinguishable clinically from cases of variola minor; but unvaccinated persons infected through contact with them suffer from unmodified variola major.

In alastrim there is essentially the same clinical picture as in variola major. The prodromal or pre-eruption illness may be quite severe, but hemorrhagic or toxic cases are rare. Marsden (1948) records only 3 among 13,686 patients, and 2 of these died In only 19 was the eruption confluent The lesions of the focal rash in alastrim tend to be more superficial and develop more rapidly, so that the eruptive phase of the illness tends to be shorter than in classic smallpox In many cases of alastrim there may be no secondary fever during the pustular stage.

The pregnant woman seems to fare particularly badly when she contracts smallpox Abortion is common because of the tendency to uterine hemorrhage which the toxemia engenders. The fetus may escape this risk but acquire infection in utero at the time of onset of illness in the mother when viremia is present. When infection takes place near the end of pregnancy the child may develop clinical disease within a few days after birth, or infection may be acquired at the time of birth if the disease is still active in the mother. A few rare instances have been recorded of smallpox in babies who were infected in utero a few days before birth, although the mother showed no clinical signs of disease (Bancroft, 1904, Lynch, 1932)

The patients who die in the first week of illness often show signs of edema of the lungs due to heart failure, and terminal pneumonia may be present But in some of these cases there may be no signs of bacterial infection, and in these death is due to the toxic effects of an overwhelming virus infection However, the majority of deaths, occur in the pustular stage toward the end of the second week An encephalitis with severe perivascular demyelination similar to that occasionally associated with vaccination and with measles may occur between the 8th and the 15th day of disease as an uncommon complication in both variola major and minor (Marsden, 1948).

The variation in mortality in different clinical types of variola major infection are well illustrated by the figures from the Minneapolis outbreak in 1924 and 1925 recorded by

Sweitzer and Ikeda (1927) Among the 1,430 cases the over-all mortality was 25 5 per cent Of 581 cases admitted to one hospital, 246 died This hospital group was subdivided as follows 10 unclassified type, no deaths, 225 discrete type, 14 deaths, 151 confluent type, 68 deaths; 144 hemorrhagic type, 113 deaths, 51 purpuric type, 51 deaths A similar mortality rate in relation to clinical types was recorded by Dixon (1948) in 500 cases studied in an outbreak in Tripolitania in 1946

Pathology

The site of entry of the virus is believed to be in the upper respiratory tract, and during the incubation period it probably multiplies in lymphoid and other internal tissues The patient is not infectious during the incubation period, so that it is unlikely that there is an open lesion in the respiratory mucosa At or just before the onset of illness there is viremia and from the circulation the virus localizes in the skin, the mucous membranes and other tissues where lesions are shortly to appear Soon after the focal skin eruption appears the patient's condition improves, the temperature drops, and neutralizing antibodies become detectable in the serum By then, the virus has multiplied within the epithelial cells in the focal lesions in the skin, and scrapings made at this time show enormous numbers of elementary bodies in appropriately stained smears Virus within cells is protected from the action of antibody so that destruction of cells goes on with consequent inflammatory changes The secondary rise of temperature associated with the stage of pustulation is probably due to the absorption of the toxic products of widespread cell necrosis

Little has been added to our knowledge of the histology of the specific lesions in the skin and the mucous membranes since the classic work of Councilman et al (1904) Their findings have been, for the most part confirmed by recent studies on material from 177 fatal cases of variola major (Bras 1952) The histology of the skin lesions in alastrim, based on the examination of 25 skin biopsies from 18 cases of alastrim at various stages of the disease, have been described by de Jong (1956) The earliest change to be observed in the skin is dilatation of the capillaries in the papillary layer of the corium with swelling of the lining endothelium There is a perivascular infiltration with lymphocytes and histocytes Changes then appear in the overlying epidermis At first a few cells in the middle layer of the epidermis become enlarged, and vacuoles appear in the cytoplasm which stains poorly The nucleus condenses and later disappears There is proliferation of cells in the malphigian layer and this, together with the swelling of cells, leads to great thickening of the epithelial layer As the process of degeneration spreads to neighboring cells in the middle layer there is intercellular edema, the cell membranes rupture and a vesicle is formed The vesicle tends to be loculated with septa formed by the remains of incompletely destroyed cells The epithelial cells beneath the vesicle are at first compressed and disorderly, but individual cells or groups of cells get detached and become rounded off The nuclei shrink, and the cytoplasm becomes more eosinophilic In the fully developed vesicle the roof is formed of compressed cells of the stratum spinosum, the keratohyalin layer and the horny layer and is very thin over the summit of the vesicle The base is formed of degenerate rounded cells of the malphigian layer which may later disappear, so that the pock cavity extends to the corium Pustules form when polymorphonuclear leukocytes enter the vesicle from the dermis, and the septa which previously crossed the vesicle disappear In the healing stage fluid is absorbed from the pustule and the contents dry up Epithelial cells from the sides of the cavity encroach upon it and proceed to grow under the residual mass of the exudate so that finally a crust is left of degenerated epithelial cells, leukocytes and debris The crusts separate in the 3rd week of illness The pitting, which is for the most part confined to the face even in severe cases, is caused, according to Bras (1952) by destruction of sebaceous glands followed by organization and subsequent shrinking of granulation tissue In cases of purpura variolosa extravasated blood cells are present in the corium, and even when no skin lesions have been obvious to the naked eye at the time of death, small areas of degeneration with commencing vesicle formation are to be seen in the epidermis microscopically Guarnieri bodies may be found in the swollen epithelial cells

In the mucous membrane of the pharynx, the uvula, the cheeks, the tongue, the larynx and the upper part of the esophagus and the trachea, lesions are to be found concurrently with those in the skin In hemorrhagic cases there may be associated hemorrhages in the submucosa No vesicles are formed, but necrosis of the epithelium occurs in small focal

lesions or may involve extensive areas of the mucosa. Because of the absence of an impervious keratinized layer the damaged epithelial cells are shed from these lesions at an early stage in the disease so that the patient first becomes infective from this source. Around the necrosed cells there is congestion and fibrinous and polymorphonuclear exudate; very soon the necrosed tissue sloughs off, leaving mucosal defects. These finally heal by growth of new epithelium and without scarring Small areas of necrosis are sometimes to be found in lymphoid tissue in the submucosa in the pharynx, the tonsils and the paratracheal lymph glands. Within the sinusoids of the liver, the sinuses of the spleen and the lymph nodes and the capillaries in the kidney and other organs large mononuclear basophilic cells are constantly present; these cells are regarded by Bras (1952) as large *lymphocytes and plasma cells having* their origin in the spleen and the lymph glands Focal interstitial accumulation of these cells in various organs is a constant and characteristic feature In the bone marrow neutrophilic polynuclear cells are scarce, and there is reactive proliferation of reticulum cells *Sometimes the marrow is normoblastic*

In the heart, apart from subendocardial hemorrhages and occasional collection of mononuclear cells around small vessels, pathologic changes are infrequent Councilman et al. (1904) commonly found bronchitis and bacterial bronchopneumonia, and Sweitzer and Ikeda *(1927) considered bronchopneumonia* as the cause of death in their 9 patients coming to autopsy On the other hand, in Bras's (1952) series of 177 autopsies, although hyperemia was common in the lungs, in only 25 was bronchopneumonia sufficiently developed to be considered as the cause or concurrent cause of death The fact that in Bras's series, nearly all the patients had had antibiotic treatment probably accounts for the difference in the findings.

The liver is constantly enlarged, but apart from occasional small hemorrhages gross changes are not obvious. The endothelial cells lining the sinusoids are frequently swollen and proliferating, and in the portal spaces there is an accumulation of lymphocytes with a few plasma cells and large mononuclears

The spleen is usually larger than normal and congested. Microscopically, the follicles appear to be hyperplastic, and in the pulp few neutrophilic granulocytes are to be seen. There is evidence of proliferation of reticulum cells, and numerous large lymphoid cells are present. In the kidneys some dilatation of the vessels and degeneration of epithelial cells is to be found, especially in the outer pyramidal zone. Focal necrotic lesions were frequently observed in the testes by Councilman et al (1904), and Bras (1952) noted that focal lesions, not readily detectable with the naked eye, were most prominent in patients dying during the pustular stage of the disease.

Cytoplasmic inclusions are characteristic of infection with variola and vaccinia viruses They may be demonstrated in various tis-

affected skin and mucous membranes. Early in the disease, in sections stained with hematoxylin and eosin, these inclusions appear as round or oval homogeneous faintly basophilic *or acidophilic masses (Guarnieri bodies)* lying in the cytoplasm, usually close to the nucleus. There may be one or more to a cell, and each is usually surrounded by a clear unstained halo These bodies are typically seen in the corneal epithelium of animals infected with variola or vaccinia viruses In *older lesions, however, both in variola* and in the skin of the rabbit infected with vaccinia the inclusions have a granular appearance, an irregular outline and may occupy a large part of the cytoplasm of infected cells (Downie and Dumbell, 1947) The appearance of the cytoplasmic inclusion varies not *only with the stage of infection* but with the methods of fixation and staining used in the preparation of sections Goodpasture et al (1932) concluded that the acidophilic cytoplasmic inclusions seen in sections were produced, in part at least, by the heaping up of masses of virus particles. The observations of Himmelweit (1938) on the development of vaccinia in the chorio-allantois, the tissue culture studies of Bland and Robinow (1939) and recent work with the electronmicroscope [illegible] that [illegible] masses [illegible] mount

of matrix. Intranuclear inclusions have been described in the lesions of smallpox in man and monkeys (Magrath and Brinckerhoff, 1904; Torres, 1935-36) but they are not a conspicuous feature of the lesions. They are not mentioned by Bras (1952) but have been found by the writer in sections of the skin from 2 of 9 fatal cases of variola major ex*amined They have not been identified in* infected chorio-allantois The relationship of

these intranuclear inclusions to the virus is unknown and may be independent of the virus itself. Differences in the staining properties of the inclusions in variola major and variola minor reported by Torres (1935-36) have not been observed by de Jong (1956)

In older studies on smallpox the importance of bacterial infection as a cause of death was emphasized, and the morbid anatomy was complicated by evidence of superadded infection with streptococci and other organisms Recent observations indicate that although bacterial infection and particularly bronchopneumonia may contribute to a fatal issue, it is not an essential feature of the pathology, nor is it responsible for the high mortality in variola major Although antibiotic treatment was used in the outbreaks in Britain during the years 1949-53, there were 32 deaths among 115 cases (mortality 28%) Blood cultures made before death from fulminating cases frequently fail to reveal bacteria, and cultures from unbroken pustules are usually bacteriologically sterile The polymorphonuclear exudate in skin pustules and in the lesions of mucous membranes is, as Councilman et al (1904) believed, secondary to cell necrosis due to the specific action of the virus.

Experimental Infection, Host Range

The infection which resulted from the inoculation of smallpox matter into human skin during the period of variolation in Europe and America has been mentioned in an earlier section The monkey appears to be the only animal other than man to contract variola under natural conditions An epidemic of smallpox in Brazil is reported to have been associated with an epizootic among Mycetes and Cebus monkeys in the area, the bodies of sick and dead animals were covered with variolous pustules (Blaxall, 1930) An orangutan (*Simia satyrus*) which lived in the zoo and contracted smallpox during an outbreak in Djakarta in 1951 is mentioned by Bras (1952)

Experimental inoculation of variolous material into the skin of monkeys results in a typical local lesion followed in some animals by a rise in temperature on the 6th and an exanthema on the 8th day (Brinckerhoff and Tyzzer, 1906) General disease may follow inhalation of dried variolous exudate or inoculation by scarification of the tracheal mucosa and less commonly after inoculation on the mucosa of the nose, the lip or the palate

Other animal species are only slightly susceptible to variola virus The work on this subject has been confused by the fact that experiments have usually been carried out in laboratories engaged in work with vaccinia virus to which animals, notably the rabbit and the calf, are highly susceptible. As a result many reports of so-called primary isolation of variola virus in animals and its subsequent transformation to vaccinia during passage are now discounted Inoculation of fluid from smallpox pustules on the cornea of the rabbit frequently produces a keratitis with the formation of typical Guarnieri bodies in affected corneal epithelium, this is the basis of Paul's test which has been used as a diagnostic procedure After intracutaneous injection of variolous material in the rabbit a local lesion results similar to that produced by vaccinia virus, but in contrast with vaccinia, attempts at continued propagation in the skin fail. Variola virus may be carried through several passages by intratesticular inoculation in the rabbit, but it shows no tendency to increase in virulence or to give rise to a vaccinial variant (Nelson 1943, Downie and Dumbell, 1956) On intranasal inoculation of mice variola virus is less virulent than vaccinia and produces only minimal lesions in the lungs (Nelson, 1939)

The virus of smallpox grows well on the chorio-allantois of developing chick embryos, producing typical small grayish white pock-like lesions which do not appreciably alter in successive passages (Torres and Teixeira, 1935, Lazarus et al, 1937, Buddingh, 1938) The pocks are smaller, more convex and have less tendency to necrosis than those caused by most strains of vaccinia virus and can be readily distinguished from them (For illustrations see Nelson, 1939, and Downie and Dumbell, 1947) If the titer of the inoculum is low, the chick embryo may survive and the lesions on the chorio-allantois heal, but with larger doses, even in early passages, death of the embryo occurs on the 3rd or the 4th day after inoculation (Smadel, 1952, Helbert, 1957). The virus from alastrim cases has in general the same low virulence for animals as has the virus from variola major However, Dinger (1956) has found that variola major

virus may be recovered in greater quantity than variola minor strains from 4 to 6 days after inoculation of comparable infecting doses on the chorio-allantois This may be related to the greater virulence for chick embryos of variola major strains reported by Helbert (1957)

Etiology

The variola virus has not been studied nearly as intensively as the closely related vaccinia virus Until the development of techniques using the chick embryo, human cases of smallpox or experimentally infected monkeys were the only sources of material for study, and monkeys were the only suitable experimental animals The chick embryo chorio-allantois has provided a readily available medium for studies during the past 20 years

The virus of variola was first demonstrated microscopically in variolous lymph by Buist in 1887 (Gordon, 1937) From their appearance in stained preparations he estimated the virus particles to be about 0 15 μ in diameter The bodies were again described by Paschen in 1906. He believed that these minute bodies were the virus and that their demonstration in stained smears from lesions in the skin and mucous membranes was of diagnostic value in smallpox Subsequent work has confirmed Paschen's view The elementary bodies are small spherical structures having a diameter of approximately 200 mμ They can be demonstrated in large numbers in smears from the early skin lesions of smallpox by staining with aniline dyes or by silver impregnation methods They are readily visible by darkground illumination or by phase contrast microscopy By electronmicroscopy the virus particles in smallpox crust extract and in smallpox vesicle fluid are indistinguishable from the elementary bodies of vaccinia virus (Nagler and Rake, 1948, van Rooyen and Scott, 1948)

Variola virus is quite stable In exudates from smallpox cases the virus has long been known to be resistant to drying Dried powdered crusts were used in China to produce immunizing infections, and matter from pustules dried on threads and kept in closed vials for months was known to be effective for variolation Living virus can be isolated from crusts kept at room temperature for over a year; from vesicle or pustule fluid dried on glass slides virus can be recovered after several months. Refrigeration is unnecessary when such specimens are transmitted by post to the diagnostic laboratory The survival of virus on bedclothes of patients has been responsible for transmission of smallpox to laundry workers (Stallybrass, 1931, Cramb, 1951) When diluted in broth and kept in sealed tubes vesicle fluid remains infective for years at 4° C. or −20° C The virus is relatively resistant to 50 per cent glycerol, to phenol and some of the common disinfectants but susceptible to oxidizing agents such as potassium permanganate. The infectivity (for the monkey) of variolous crusts suspended in saline solution is destroyed at 55° C in half an hour (Gordon 1925) Cross-immunity experiments in monkeys show that the viruses of variola, alastrim and vaccinia are immunologically similar. Soluble antigens of variola virus are demonstrable in fluid from smallpox vesicles, in extracts of dried crusts and of infected chorio-allantoic membranes by precipitation or complement-fixation tests using smallpox convalescent serum or rabbit antivaccinial serum These serologic reactions are used in diagnostic tests While the soluble antigens of variola have not been studied as carefully as those of vaccinia, they are practically identical in reactivity with immune sera Hemagglutinin is produced by variola virus, although on the infected chorio-allantois its titer is lower than is the vaccinia hemagglutinin from the same source (North, 1944). No difference between these hemagglutinins has been detected by inhibition tests with immune sera Further reference is made to the immunologic relationships of variola and vaccinia in the section dealing with vaccinia virus

Diagnosis

In the majority of cases of smallpox the diagnosis can readily be made on clinical grounds During the eruptive phase the following points are of importance: the size and the evolution of the lesions within accepted time limits through various stages, the distribution of the eruption over the skin surface, the evidence of progressive eruption with older lesions on the face and the arms and the more recent on the lower limbs but the lesions being homogeneous on any one part The history of a severe febrile pre-eruptive illness

lasting 2 to 4 days is usual, and a definite or possible history of contact with a previous case should be sought for. The clinical diagnosis cannot be made with certainty during the pre-eruptive illness, but such illness in smallpox contacts should be regarded provisionally as variolous. When a diagnosis of smallpox is considered on clinical grounds preventive measures should be instituted without waiting for laboratory tests. The 2 types most likely to be overlooked are the acute hemorrhagic patient who dies before the focal eruption appears and the modified case with a very sparse or atypical eruption in a previously vaccinated individual. The acute hemorrhagic case may be mistakenly diagnosed as acute purpura, typhus, hemorrhagic scarlet fever or acute meningococcal septicemia. The case of variola major modified by previous vaccination, or alastrim in a vaccinated or unvaccinated person, may be confused most commonly with varicella, with pustular acne, with drug eruptions, particularly a pustular sulfonamide rash, or with erythema multiforme and Stevens-Johnson syndrome. Vaccination as a diagnostic procedure may be useful, for less than 10 per cent of smallpox cases can be vaccinated on the first day of the focal rash, and none after the 6th day (Marsden, 1948). If after careful consideration of the history and the clinical picture the diagnosis is still in doubt, the virus laboratory can give valuable assistance.

The laboratory procedures which have been found useful in recent years are directed to: (1) the detection of virus, (a) by direct microscopic examination of material from lesions in the skin and the mucous membranes, or (b) by inoculation on the chorio-allantois of developing chick embryos of material from the blood or skin lesions, (2) the demonstration of specific antigen in focal lesions, and (3) the demonstration of antibody or increase of antibody in the blood during the course of

the illness Table 30 illustrates the material to be sent and the tests likely to give a positive result at various stages of the disease. Details of the method of collecting specimens and the technics used in their examination are to be found in articles by MacCallum (1954) and Kempe (1956). Downie and Macdonald (1953) have recorded the results obtained by the various tests in series of cases of variola major and variola minor.

The presence of elementary bodies in smears from lesions was first used as an aid to diagnosis by Paschen, and the test was found to be of special value by van Rooyen and Illingworth (1944) during an outbreak of smallpox in the Middle East. Much depends on the care with which the preparations are made and the experience of the virologist. Smears on clean slides should be made with material obtained by scraping with the point of a knife or a Hagedorn needle maculopapular lesions or the base of vesicles or pustules Paschen's or Gutstein's staining methods give satisfactory results, but the appearances may be difficult to interpret in preparations from pustules owing to the presence of granular debris However, satisfactory results with such material may be obtained by using Gispen's (1952) modification of Morosow's silver impregnation method (de Jong 1956). The finding of numerous typical elementary bodies in microscopic preparations may enable a presumptive positive report to be sent to the physician within an hour of receipt of the specimen at the laboratory Such a finding should be confirmed by the isolation and the identification of virus on the chorio-allantois or by serologic test for specific antigen if suitable material from the patient is available. A negative finding on microscopic examination is of much less value and should be ignored if the clinical picture favors a diagnosis of smallpox. Preparations from vaccinial lesions give the same microscopic picture as those from variola. Material from cases of varicella or herpes simplex reveals few, if any, elementary bodies, and when present they appear smaller and stain less deeply. The virus particles from the lesions of variola may be demonstrated by the electronmicroscope, but this technic is not practicable for routine work in most laboratories.

The isolation and the identification of virus by use of the chick embryo, first used as a routine diagnostic method by Bohls and Irons (1942), is more easily and more certainly effected than by the inoculation of the rabbit cornea. The lesions which variola virus produces on the chorio-allantois are visible after 48 hours but become more typical after 72 hours The specific nature of the lesions should be confirmed by histologic examination and serologic testing of an extract of the membrane by complement-fixation with rabbit antivaccinial serum. The naked-eye appearances of the lesions will usually enable a diagnosis to be made as between variola and generalized vaccinia occurring during a smallpox outbreak. Where doubt remains the differentiation may be made by inoculation of an extract from the infected chorio-allantois into the skin of a rabbit. Lesions may be produced in this tissue by both viruses, but passage to a fresh rabbit will succeed if the material is vaccinial and will fail if it is variolous. A very small amount of material from smallpox cases will give a positive result on the chorio-allantois Smears on glass slides from macular to pustular stage of the eruption, extracted with saline and used for inoculation will almost invariably produce typical pocks. Extracts from crusts are likewise suitable in late cases which have not been diagnosed early in the disease. During the first few days of the febrile illness virus may be isolated from the blood A positive result was obtained at this stage in all 4 hemorrhagic cases examined by Downie et al (1953), and virus was found during the first few days in the blood of most patients who subsequently died. On the other hand, with the technic used, virus was found in the blood early in the illness of only 4 of 25 patients who recovered Material from varicella patients produces no obvious lesions on the chorio-allantois The fluid from the skin eruption in the rare cases of generalized herpes simplex infections will provoke lesions on the chorio-allantois These can be distinguished as a rule by their smaller size and by histologic examination; extracts of the infected membranes give a negative complement-fixation test with antivaccinial serum

The detection of specific antigen in material from skin lesions is made by the complement-fixation technic using as antibody antivac-

cinial serum prepared in the rabbit. Present procedure is based on that used by Craigie and Wishart (1936a) The test always gives a positive result in smallpox cases if sufficient material is available for examination The fluid from 6 vesicles or pustules or 6 crusts should provide an adequate specimen A positive result may be obtained with less material, even with extracts from a few smears on glass slides, but a negative result from inadequate material is of no diagnostic value Fortunately, virus can usually be recovered by egg inoculation from material which is too small in amount to give a reliable serologic test The test for antigen can be recorded only as positive or negative for variola-vaccinia antigen and will not serve to distinguish the occasional case of generalized vaccinia from smallpox In hemorrhagic cases of smallpox both complement-fixing antigen and virus may be found in the blood during the first few days of illness (MacCallum et al, 1950) So far, antigen has not been detected in the serum of patients who are to recover (Downie et al, 1953).

The test for antibodies in the patient's serum may be of value in the diagnosis of atypical or mild cases who have been overlooked at the beginning of an outbreak or in cases of *variola sine eruptione* In this latter type of infection the test for antibody is the only laboratory procedure likely to be of assistance in establishing the diagnosis The specific antibody may be measured by estimating the highest dilution of the serum which will inhibit vaccinial hemagglutination of selected fowl cells or will fix complement in the presence of specific vaccinial or smallpox antigen Collier et al (1950), who used buffalo vaccinial pulp as a source of hemagglutinin, found that specific antihemagglutinins appeared in the serum of smallpox patients about the 5th or 6th day of illness By the complement-fixation technic antibody is not usually detected until the 8th or 9th day The patient who has been previously vaccinated may show a rise in serum antibody several days earlier than antibody appears in the serum of the unvaccinated patient In previously vaccinated individuals a 4-fold or greater rise in titer of antibody, as demonstrated by the examination of 2 serum samples taken some days apart, would be more useful than the test on a single specimen In unvaccinated persons inhibition of vaccinial hemagglutinin at a serum dilution of 1 80 or higher and complement-fixation in a serum dilution of 1 10 or higher would be regarded as indicative of infection with variola, cowpox or vaccinia virus

Histologic examination of biopsy specimens from skin lesions may serve to distinguish cases of modified variola major or alastrim from cases of varicella (de Jong, 1956) In the varicella vesicle its more superficial situation, the absence of reticular degeneration, the presence of multinucleated epithelial cells and the intranuclear inclusions are characteristic and serve to distinguish it from the smallpox lesion

The tests described above are applicable equally to the diagnosis of variola major and variola minor but do not serve to distinguish between them The recent observations of Dinger (1956) and Helbert (1957) indicate that they may be differentiated by careful study of the virulence for the chick embryo of the virus isolated and comparison with known strains from both forms of smallpox

Treatment

No specific therapy for variola is available The use of sulfonamides and antibiotics is indicated in the treatment and the prevention of bacterial complications It has been suggested that the use of these drugs modifies and diminishes the pustular eruption, but controlled trials have not been reported Convalescent smallpox serum has been used in the treatment of severe cases in doses of 30 to 50 ml but without obvious beneficial result (Illingworth and Oliver, 1944, Easton, 1945) The use of immune gamma globulin in the prophylaxis of smallpox is referred to in the section on control

Epidemiology

The ultimate source of infection in smallpox is the person suffering from the disease The contact may be direct or indirect through utensils, clothing or dust infected by the patient There is no evidence that the patient is infective during the incubation period Infected contacts have been allowed freedom of movement among their fellows during their incubation period without spreading the disease (Dixon, 1948) From the public health

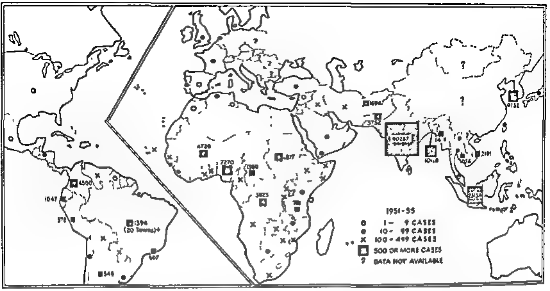

FIG 114 Smallpox, 1951-1955 Annual average of officially reported cases (Modified from Gear, H. S., and Deutschman, Z., 1956, *Disease Control and International Travel*, Geneva, World Health Organ)

point of view the smallpox patient must be regarded as potentially infectious from the onset of illness until the last scabs have dropped off, but epidemiologic observations suggest that most patients become infectious only with the appearance of the focal rash, a view held by Ricketts and Byles (1908) and supported by recent experience By the time the eruption appears there is a large amount of virus in the lower layers of the epidermis, but the impermeable nature of this tissue prevents the virus from reaching the exterior until rupture of vesicles and pustules

early erosion of lesions on the mucous membranes ensures heavy contamination of the saliva and mucous secretions. the virus may be demonstrated in the saliva when the focal rash appears but not usually before. Purpuric cases of smallpox, in whom hemorrhages may occur from mucous membranes soon after onset of illness, may be infectious throughout the febrile illness (Stallybrass, 1931). Therefore, in the early stage of the focal eruption, infection is spread from the mouth and the nose and later from the skin lesions. Because of the resistant nature of the virus, infec-

cotton. MacCallum and McDonald (1957), who have studied the survival of virus in smallpox scabs wrapped in cotton and kept at temperatures from 30° to 40° C. or higher, found that virus did not survive longer than 6 months; but at 20° to 25° C virus could be recovered after 17 months It may be that contacts protected by vaccination and showing no signs of illness may temporarily spread infection A more dangerous source is the vaccinated person whose immunity has waned and whose smallpox infection is so mild that medical help is not sought, or whose infection is atypical and mistaken for varicella The first cases in the 1950-51 outbreak mentioned above and in the Glasgow outbreak of 1950 (Laidlaw and Horne, 1950) illustrate the importance in the spread of smallpox of mild illness in partially immune persons

Unvaccinated persons of all races and ages are susceptible to smallpox The disease may occur at all seasons in the year but is more common in the colder months of winter and spring than in summer. Smallpox is still endemic in large areas of the world but especially in India, some areas of southeast Asia, parts of Africa and some of the countries of South America Other countries are at risk from these reservoirs of infection Movement

demic infections. During and immediately

after World War II there was some spread of smallpox particularly in Africa and Asia (Fabre, 1948), but since then the incidence of the disease has diminished in many countries (Gear and Deutschman, 1956) Figure 114 shows the average annual incidence of officially reported cases in various parts of the World during the years 1951-1955 During this period Europe has suffered little, apart from sporadic outbreaks due to importations from Asia or Africa, and in 1956 no cases were reported in Europe, although information was not available from Albania East Germany, Bulgaria, Poland Rumania or Czechoslovakia (Report 1957) In the U S A the incidence of smallpox was high during the 1920-30 decade, subsequently, there was a remarkable fall in the number of cases recorded (Fig 115) From the year 1945 when there were 346 cases the numbers steadily diminished There were only 4 cases in 1953, and no case of smallpox was recorded in 1954, 1955 and 1956 In certain of the countries of South America (Venezuela, Peru and Chile) the position in recent years has greatly improved coincident with the institution of more general vaccination (Gear and Deutschman, 1956)

Variola major and variola minor seem to be equally infectious But control of the milder disease is more difficult because notification is apt to be incomplete, and missed cases, ambulant while still infectious, tend to prolong an outbreak This is illustrated by the experience of smallpox in Britain in the years 1944-53 Many small outbreaks of variola major resulted from importations into England, the largest number in any one outbreak being that in 1953 (30 cases with 8 deaths) However, the alastrim outbreak in 1951-52 extended over 4½ months, there were over 140 cases but no deaths

Control Measures

Measures for the control of smallpox recommended by the American Public Health Association (1955) have been approved in principle by the U S Public Health Service and the Armed Forces as well as by departments of health of foreign governments These recommendations are made under 4 headings and are summarized below

A Preventive Measures

1 Vaccination at about 3 months of age with revaccination at school entry and on exposure to high risk of infection

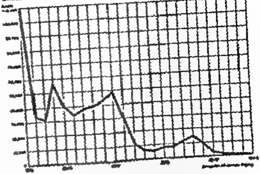

Fig 115 Cases of smallpox reported in the United States, 1921-1944 (Dublin, L I, 1945, The conquest of smallpox, Statistical Bulletin Metropolitan Life Insurance Company *29*, 8)

2 Measures to ensure available supply of potent lymph kept below freezing point to maintain potency

3 Vaccination by multiple pressure on small area of skin over deltoid preferred, no dressing need be applied Children with eczema should not be vaccinated or come into contact with recently vaccinated persons After revaccination examination should be made at 3rd and 9th days to determine whether reaction is of primary, vaccinoid or early (immediate) type Early reaction difficult to interpret If in doubt revaccinate If no reaction always revaccinate

B Control of infected individuals, contacts and environment

1 and 2 All cases to be reported to Health Authority and isolated in hospital until all crusts have disappeared

3 and 4 All oral and nasal discharges and articles associated with patients to be disinfected by burning, high pressure steam or boiling

5 and 6 All contacts at home, place of work or elsewhere to be vaccinated or revaccinated with potent lymph and kept under surveillance for 16 days from time of last contact Any rise of temperature during surveillance calls for prompt isolation until smallpox can be excluded

7 The immediately prior case should be sought assiduously Adult chickenpox or patients with hemorrhagic or pustular lesions of the skin need careful review for errors in diagnosis

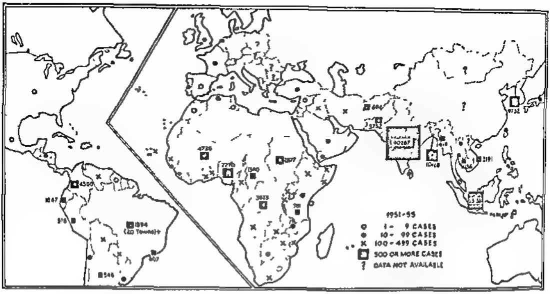

FIG 114 Smallpox, 1951-1955. Annual average of officially reported cases (Modified from Gear, H. S., and Deutschman, Z., 1956, Disease Control and International Travel, Geneva, World Health Organ)

point of view the smallpox patient must be regarded as potentially infectious from the onset of illness until the last scabs have dropped off, but epidemiologic observations suggest that most patients become infectious only with the appearance of the focal rash, a view held by Ricketts and Byles (1908) and supported by recent experience. By the time the eruption appears there is a large amount of virus in the lower layers of the epidermis, but the impermeable nature of this tissue prevents the virus from reaching the exterior until rupture of vesicles and pustules occurs at a later stage However, in the mouth and the upper respiratory passages there is no impermeable layer on the surface, and the early erosion of lesions on the mucous membranes ensures heavy contamination of the saliva and mucous secretions: the virus may be demonstrated in the saliva when the focal rash appears but not usually before Purpuric cases of smallpox, in whom hemorrhages may occur from mucous membranes soon after onset of illness, may be infectious throughout the febrile illness (Stallybrass, 1931). Therefore, in the early stage of the focal eruption, infection is spread from the mouth and the nose and later from the skin lesions. Because of the resistant nature of the virus, infec- [illegible]

shire, England, have been traced to imported cotton. MacCallum and McDonald (1957), who have studied the survival of virus in smallpox scabs wrapped in cotton and kept at temperatures from 30° to 40° C or higher, found that virus did not survive longer than 6 months, but at 20° to 25° C virus could be recovered after 17 months. It may be that contacts protected by vaccination and showing no signs of illness may temporarily spread infection. A more dangerous source is the vaccinated person whose immunity has waned and whose smallpox infection is so mild that medical help is not sought, or whose infection is atypical and mistaken for varicella The first cases in the 1950-51 outbreak mentioned above and in the Glasgow outbreak of 1950 (Laidlaw and Horne, 1950) illustrate the importance in the spread of smallpox of mild illness in partially immune persons

Unvaccinated persons of all races and ages are susceptible to smallpox. The disease may occur at all seasons in the year but is more common in the colder months of winter and spring than in summer. Smallpox is still endemic in large areas of the world but especially in India, some areas of southeast Asia, parts of Africa and some of the countries of South America Other countries are at risk from these reservoirs of infection. Movement of populations, the disruption of public health control measures and other factors associated with war tend to favor the spread of endemic infections During and immediately

ice personnel were not always reliable, certainly less reliable than the evidence of vaccination scars (Easton, 1945; Waldo, 1955). The occurrence of smallpox in soldiers recorded as having been successfully vaccinated gave rise to some doubt as to the ability of the vaccine then in use to protect against the virulent strains of variola virus encountered. However, the fatal cases of smallpox in outbreaks among troops in the Middle East and the Far East where data were recorded were usually devoid of vaccination scars.

It should be emphasized that faulty vaccine or faulty technic may result in failure to produce a reaction on human skin. Such absence of reaction should not be regarded as evidence of immunity but as an indication of the need for revaccination with potent lymph. Easton (1945) records of one man who died of confluent smallpox that vaccination had been attempted at birth, again in 1941 and 10 times in 1943 without a take, thus emphasizing the danger of accepting even repeated unsuccessful vaccination as evidence of insusceptibility to smallpox.

Vaccination is a relatively safe and very effective immunizing procedure. The serious complications which may occasionally follow are generalized vaccinia and postvaccinial encephalitis. Serious infection with pyogenic bacteria and postvaccinial tetanus are rarely encountered today. Generalized vaccinia occurred in 45 persons following the mass vaccination of 5,000,000 persons in New York during 2 months in 1947 (Greenberg, 1948). Of the 45 cases of generalized vaccinia, 38 had a pre-existing dermatosis, and 28 of them had not been vaccinated but were accidentally infected through contact with vaccinated persons. Of the last group 2 babies under 1 year of age died. Among the 5,000,000 vaccinated, 44 cases and 4 deaths were attributed to postvaccinial encephalitis. In the 4 patients who died histopathologic examination did not show changes typical of postvaccinial encephalitis. The incidence of this complication varies at different times and in different countries (Stuart, 1947-48). In Scotland following smallpox outbreaks in 1942 the incidence of postvaccinial encephalitis in Glasgow was 1 per 70,000 vaccinations, and in Edinburgh and district 1 per 21,000 vaccinations. In Holland the incidence has been unusually high, but the cause of this is unknown. It is believed to be uncommon in the first year of life, but Herrlich (1954) records an incidence of 1 in 17,400 vaccinations under 1 year of age in Bavaria for the years 1945-1953.

Immunity following successful vaccination develops rather more quickly than that following smallpox infection by the usual route, and it has been maintained in the past that successful vaccination within 3 days after exposure would protect previously unvaccinated contacts against smallpox. While this may have some general validity there are exceptional cases, for smallpox has been recorded in contacts successfully vaccinated within 1 day after exposure. Of 1,083 cases of variola minor, who had been vaccinated successfully after exposure to infection, the focal rash appeared in 89 patients on the 12th day, in 17 patients on the 13th day, in 5 patients on the 14th day, and in 1 patient on the 15th day after the vaccination (Marsden, 1948). Such observations serve to stress the need to avoid delay in the vaccination of smallpox contacts. The time of appearance and duration of immunity following vaccination is variable, and whether or not smallpox develops in a vaccinated person depends not only on the nature of the person's immunity response to the vaccination but also on the intensity of subsequent exposure to infection. Revaccination at frequent intervals is advisable for persons exposed to high risk of infection, such as troops serving overseas in endemic areas. The need for vaccination and revaccination of the staffs of hospitals is forcefully emphasized by 2 outbreaks in British hospitals which had admitted missed cases of variola. Of the total of 48 cases of smallpox in those outbreaks 23 were members of hospital staff, and 11 of these died (Laidlaw and Horne, 1950; Cramb, 1951).

The standard smallpox vaccine is glycerinated calf lymph or, in England, glycerinated sheep lymph. These glycerinated lymphs must be stored by the manufacturer at $-10°$ C. After distribution, vaccine may be used in the U.S.A. up to 3 months if stored below 10° C. More stable preparations are needed, especially in the tropics where refrigeration during storage and transportation is difficult. Dried buffalo lymph prepared by Otten et al (1950) has been used successfully on a wide

C. Epidemic measures.

1 and 2 Hospital isolation of cases and suspects until no longer infectious. Careful listing of all contacts, vaccination and surveillance for 16 days.

3 Immediate publicity by available methods giving frank statement of situation and urging individuals in area to be vaccinated. Provision of potent vaccine and arrangements for vaccination

4. Mass immunization of whole population of community or larger area is an emergency measure to be used when an outbreak has given evidence of material spread.

D. International measures

1 Telegraphic notification of W.H.O. and adjacent countries of existence of epidemic of smallpox

2 Measures applicable to ships, aircraft and land transport arriving from smallpox areas are specified in International Sanitary Regulations (W.H O Techn Rept Ser. No. 41 Geneva, 1951).

3 Evidence of a previous attack of smallpox or of recent vaccination or revaccination (within a period of 3 years) is a widely enforced requirement for entry to or departure from a country

The smallpox vaccine in common use is prepared from the vaccinial lesions on the skin of inoculated calves or sheep, and contains infective virus Methods to be used in its preparation, preservation and storage until used for vaccinating human beings against smallpox are carefully controlled Regulations in force in the United States regarding these matters have been set forth by the National Institutes of Health (1946) For the United Kingdom they are embodied in the Therapeutics Substances Regulations, 1952, No. 1937, amended by Regulations 1957, No. 550. (London Her Majesty's Stationery Office.)

The reactions resulting from the inoculation of smallpox vaccine are of 3 general types: namely, primary, vaccinoid or accelerated and early or immediate (previously called immune) These 3 types of reaction at different stages of their development were well illustrated in the colored plate (page 424) in the 2nd edition of this book (1952) A primary reaction is that which normally follows in a person who has not previously had experience of smallpox, cowpox or vaccinia virus. Until the 4th day following vaccination there is no reaction. Then a small papule appears which rapidly becomes a vesicle. This enlarges in size, and there develops around it a zone of erythema of variable width. The center of the vesicle usually becomes depressed, and by the 8th or 9th day the contents become turbid, and there may be associated axillary adenitis with some degree of fever The reaction reaches its maximum extent usually between the 8th and the 10th days, after which the pustule dries up, and a scab forms which may take a week to separate This reaction is usually followed by a variable degree of immunity to vaccinia and variola beginning about the 10th day and lasting for months or years. Babies born of recently vaccinated mothers possess antibodies and may show a poor response to vaccination during the first few weeks of life.

The vaccinoid or accelerated reaction following inoculation with a potent lymph is a modified reaction given by a person who has some residual immunity from a previous attack of smallpox or vaccination The maximum intensity is reached between the 3rd and the 7th days following vaccination Although the lesion is smaller than the primary reaction, vesiculation always occurs This type of response increases the waning immunity of previous vaccination

The early or immediate reaction is an indication of sensitivity to the virus and may be given by persons who are either susceptible or immune to smallpox. The reaction is most marked on the 2nd or 3rd day and diminishes thereafter. The local lesion is usually papular but may vesiculate. This response has been called an immediate reaction of immunity, but it is neither immediate nor necessarily a reaction of immunity It may occur in those whose immunity has waned and may be elicited by inoculation of dead virus (Hooker, 1929, Broom, 1947, Benenson, et al, 1952) When a potent vaccine is used the early reaction may merge into the vaccinoid reaction But the early reaction by itself cannot be regarded as a successful result and cannot be guaranteed to induce or increase the person's resistance to smallpox The interpretation of an early reaction as a successful vaccination indicating a state of immunity may have been, in part, responsible for reports of smallpox, sometimes fatal, in successfully revaccinated service personnel Vaccination records of serv-

cows the true cowpox lesion appears on the teats or on the contiguous part of the udder as small red pimples which increase in size and become vesicular, the vesicles which surmount a firm deep-seated inflamed base quickly show a depressed center and tend to be ruptured early during the operation of milking The ruptured surface becomes covered with scabs which take some time to separate, and several weeks may elapse before the lesions heal As a rule, the animals do not suffer serious general upset The disease tends to spread quickly through a herd, infection being conveyed from one animal to another in the process of milking In those attending affected animals one or more lesions may appear on the hands—the thumb, the first interdigital cleft and the forefinger being especially liable to attack, but scratches or abrasions of the skin may determine localization of the lesions elsewhere on the hands, the forearms or the face The lesions in their development resemble those of primary vaccination Local edema is often pronounced, there are lymphangitis and lymphadenitis, and there may be some degree of fever for several days, especially in those who have never been vaccinated In such persons 4 or 5 weeks may elapse before the scabs finally separate Second attacks may occur after an interval of years but in these, as in persons who have been previously vaccinated, there may be no fever or constitutional upset

Pathologic Picture and Experimental Infection

The pathologic changes produced and the natural and experimental host range are similar to those of vaccinia virus Histologically, the lesions in the skin of those infected with cowpox virus from cattle show great epidermal thickening, rather less rapid cell necrosis than in vaccinia and the presence of numerous large homogeneous strongly acidophilic cytoplasmic inclusions in the lower layers of the affected epidermis Leukocytic infiltration, congestion and hemorrhage are to be found in the dermis immediately underlying the affected epidermis The virus can readily be maintained by passage in the skin or the testicle of the rabbit, by intradermal inoculation of guinea pigs, mice or monkeys, or on the chorio-allantois of the chick embryo In all these tissues cowpox virus differs from dermal strains of vaccinia in that there is less rapid necrosis of epithelial cells which exhibit the large inclusions above mentioned, there is a greater tendency to invade mesodermal tissue, and by involvement of capillary endothelium the lesions in skin and chorio-allantois have a characteristic hemorrhagic appearance (Downie, 1939a; Dekking, 1950; Verlinde, 1951; Herrlich and Mayr, 1955) In the rabbit cornea lesions are less extensive than those produced by vaccinia There is less epithelial necrosis, and the cytoplasmic inclusions are more strongly acidophilic and much larger than classic Guarnieri bodies (Berger, 1956) In the rabbit fatal generalized infection may result from intravenous inoculation of virus, and inoculation of large doses on the chorio-allantois may lead to fatal infection of the chick embryo A variant has been isolated from cowpox strains grown on the chorio-allantois of chick embryos (Downie and Haddock, 1952, van Tongeren, 1952) This variant resembles dermal strains of vaccinia in that the lesions are associated with rapid necrosis of infected epithelium, a marked polynuclear leukocytic reaction and absence of hemorrhage, but the lesions show the large cytoplasmic inclusions characteristic of the normal cowpox strains

Etiology

The virus of cowpox is identical in size and appearance with that of vaccinia when examined by the electronmicroscope, and in so far as it has been examined it is similar in resistance to heat and chemical agents The antigens of cowpox virus have not been studied so intensively as those of vaccinia but have the same serologic reactivity The hemagglutinin is not obtained in such high titer from infected tissue but acts on the same range of fowl red cells The LS antigen (Smadel, 1952) is similar, although by cross complement-fixation tests with immune sera there is a slight difference in the soluble antigens of the 2 viruses Precipitation studies by the agar gel diffusion technic suggest that there is a quantitative difference in minor antigenic components (Gispen, 1955) Cross-absorption of anticowpox and antivaccinial sera prepared in rabbits or fowls, using living virus suspensions to absorb the sera, confirm that although there is a very large antigenic overlap there are minor antigenic differences between the strains

scale in Indonesia since 1946. Collier (1955) found that a partially purified elementary body suspension prepared from sheep pulp, suspended in 5 per cent peptone, freeze-dried and sealed in vacuo kept its potency well for some months at 37° C and 45° C. This type of vaccine, even after storage for 2 years at 37° and at 45° C., showed practically no loss of titer on the chorio-allantois or rabbit skin and gave 100 per cent successful primary takes on previously unvaccinated persons (Cockburn et al, 1957). One disadvantage of lymphs prepared in animals is the difficulty of obtaining a product completely free from bacterial contaminants. To obtain this desirable objective 2 other sources of virus have been used for the preparation of vaccine—vaccinia virus propagated in the chorio-allantois of chick embryos and in tissue culture Glycerolated vaccine prepared from virus grown on the chorio-allantois has been used in certain parts of the U.S.A. for some years After 240 continuous egg passages, however, the strain used for vaccine preparation gave milder lesions in vaccinated children and a slightly greater susceptibility to revaccination after 14 months than did calf-lymph vaccine (Buddingh, 1943) *Subsequently, satisfactory* vaccine was prepared by the egg method using as inoculum calf lymph to which penicillin and streptomycin had been added (Buddingh and Randall, 1951) Similar seed virus has been used for the preparation of egg vaccine by the Texas State Department of Health, and this vaccine has given satisfactory results in the field for a number of years (Cook et al, 1953) A method of preparing stable bacteria-free lyophilized vaccine from the chick chorio-allantois has been elaborated by Jackson et al (1956) In recent years vaccinia virus grown in tissue cultures of bovine embryo skin has been used in the preparation of smallpox vaccine (Wesslén, 1955). This method also provides a bacteriologically sterile vaccine which can be produced very economically. It has not yet been demonstrated that either of these vaccines minimizes the risk of postinfectious encephalitis, their other advantages may yet overcome the conservatism which has prevented the wider adoption of potent bacteria-free egg vaccine.

It has been indicated above that vaccination of smallpox contacts may be effected too late to ensure protection from the disease. In these cases it seems that passive protection might be achieved by the administration of immune gamma globulin early in the incubation period, as in measles. Preliminary trials of this procedure have been made by Kempe et al (1956), using gamma globulin prepared from the blood of recently vaccinated persons Among the 56 contacts in the test group who were vaccinated and given immune gamma globulin there were 2 cases of smallpox—1 fatal and 1 modified; while in the control group of 75 contacts, who were comparable in age and vaccination history with the test group and were vaccinated only, there were 8 cases of smallpox and 3 deaths Although the numbers in the 2 groups were small, the results seem to suggest that this method of prophylaxis is worthy of further trial in epidemic areas

COWPOX

History

Cowpox was first brought to the notice of the medical profession generally by Jenner's publication on this disease in 1798, but there is no doubt that it had long existed in cattle as an endemic disease which was occasionally transmitted to milkers Cowpox still occurs in Europe, but it is not a serious disease in cows and attracts medical attention when the infection is contracted by those engaged in milking or otherwise caring for the affected animals

Clinical Picture

The disease in cattle was described in great detail by Ceely (1840) who, like Jenner, was careful to distinguish true cowpox from other eruptions seen on the teats of cows It seems clear from more recent literature that, even at the present time, this distinction is not always made The so-called natural cowpox said to be prevalent in America and causing milkers' nodes in man (Hester et al, 1941; Nomland and McKee, 1952), is etiologically unrelated to Jenner's true cowpox There is no cross-immunity between the virus responsible for milkers' nodes and the virus of vaccinia (Becker, 1940, Berger, 1955), whereas cowpox virus and vaccinia are immunologically almost identical Moreover, the clinical and histologic findings in milkers' nodes are quite different from those of cowpox in man. In

us is that of herpes simplex Eczema vaccinatum may be a local infection resulting from implantation of virus on eczematous skin, but the simultaneous appearance of the eruption, the occurrence of lesions on healthy skin and the fact that the dermatitis may be quiescent at the time the vaccinial infection is acquired would suggest that blood-borne virus localizes in the abnormal areas of skin or that there is an extremely rapid spread, possibly by skin lymphatics, from the original site of virus implantation

Generalized vaccinia occurring in persons with previously healthy skin is a much rarer condition with onset between the 9th and the 14th days after vaccination The condition may resemble smallpox, although the eruption does not usually have such a marked centrifugal distribution The lesions may appear in crops over 2 or 3 days Usually, the condition is not fatal, and rapid recovery is the rule This type of generalized infection seems to be associated with delayed antibody response to vaccination

Fortunately, progressive vaccinia is very rare Following vaccination there may be a normal primary take, but the lesion does not heal Instead, it extends slowly with necrosis of tissue, and fresh vesicles appear in the neighborhood of the vaccination site or in other regions of the body The mucosa of the mouth, the pharynx and the larynx may become involved, and the child slowly loses weight but may survive for 3 or 4 months after vaccination (Bigler and Slotkowski, 1951), the successive appearance of fresh lesions on various skin areas indicates a continuing viremia, and in the case reported by Keidan et al (1953) virus was recovered from the blood on 4 occasions from the 21st to the 39th day after vaccination There may be a leukopenia affecting especially lymphocytes Histologic study of postmortem material may show a complete absence of reactive inflammation around the skin lesions, areas of focal necrosis found in lungs, liver, adrenal and kidney in the case reported by Hall et al (1953) showed a similar absence of cellular reaction. In all cases reported in which examination for neutralizing antibody has been made none has been found, in a few, though not in all, there has been agammaglobulinemia (Kempe et al, 1956)

Pathology

The lesion produced in the skin by vaccinia virus, whether in man or in animals, is histologically similar to that seen in smallpox The epithelium undergoes the same kind of changes, and when in experimental animals the skin lesions result from generalization by the blood stream, evidence of epithelial damage may be preceded by changes around the small vessels in the dermis, these show dilatation and swelling of endothelium, and there may be infiltration of mononuclear cells around them In experimental animals the nature and the extent of the lesions varies with the strain of virus, the size of the infecting dose and the route of inoculation In generalized infections lesions of the skin of the eyelids, the mucocutaneous junctions about the lips, the nares and the anus are common Areas of focal necrosis, sometimes surrounded by a zone of congestion or hemorrhage, may be encountered in liver, lungs, kidneys, ovaries and testis Lesions produced on the chick embryo chorio-allantois may be 2 to 3 mm in diameter after 3 days The infected cells in the greatly thickened ectoderm tend to become rounded off and show acidophilic inclusion material occupying a large part of the cytoplasm Inclusion bodies are found less commonly in the cells of the edematous mesoderm and in the hypertrophied endoderm If the inoculum is large, lesions may appear on the skin and the internal organs of those embryos which survive for 4 or 5 days

Experimental Infection, Host Range

A wide range of animals is susceptible to infection with vaccinia virus Apart from the infections in man which have been considered above, calves, sheep and rabbits have been regularly employed for the propagation of virus in the production of vaccine lymph for smallpox vaccination Other laboratory animals, such as monkeys, rats, mice, guinea pigs and hamsters, may also be infected, although they are less susceptible than the rabbit to strains commonly used The chick embryo may be infected by inoculation of virus on the chorio-allantois, into the amniotic cavity or into the yolk sac, although the lethal dose for the embryo by the first route may be only a hundredth of that by the other two routes (Cabasso and Moore, 1957)

Strains of vaccinia virus used for the production of smallpox vaccine in various labora-

of cowpox and vaccinia viruses so far examined (Downie, 1939b; Downie and McCarthy, 1950).

Diagnosis

Clinically, cowpox in farm workers may resemble 2 other virus infections occasionally acquired through contact with stock animals, namely, milkers' nodes from cows and contagious pustular dermatitis from sheep. These infections are less vesicular in character and are usually less severe in man than that occasioned by cowpox virus, in neither can transmission to laboratory animals be readily effected. The clinical diagnosis of human cowpox infections may be confirmed by the laboratory technics used in the diagnosis of smallpox The isolation of virus from the patient by inoculation of vesicle fluid on the chorioallantois and the appearance and the histology of the focal lesions in this tissue or in the skin of the rabbit will serve to distinguish infections caused by cowpox virus from those occasionally contracted from cows which have been accidentally infected with vaccinia strains (see below).

Epidemiology

Infection in man is acquired from infected cows and rarely spreads from person to person In a herd of cows an outbreak can often be traced to an animal recently brought to the farm from outside It has been suggested that infection in cows results from contact with a recently vaccinated person (Hamburger, 1948) That cows may be so infected and transmit the infection again to man is indicated by the findings of Dekking (1955), of 36 strains isolated from outbreaks in Holland 8 had the characters of laboratory vaccinia strains, and the remainder were typical cowpox strains All strains isolated from outbreaks in England during the last 20 years have been typical cowpox virus

Treatment and Control

There is no specific treatment The disease in cows does not appear to be sufficiently serious or widespread to warrant prophylactic vaccination.

VACCINIA

Introduction

The term vaccinia is used here to indicate the infection which is caused by the virus propagated in laboratories and used for prophylactic vaccination against smallpox. As indicated above, the history and the origin of many of the strains used for this purpose are obscure. While certain strains are alleged to have been derived from smallpox, it seems to the writer that the properties and the characters of most strains now in use suggest that they have been derived from cowpox virus, i e, the virus responsible for the pox disease of cows Strains of vaccinia virus by repeated passage in different animals or tissues may acquire characters which serve to distinguish them from vaccine lymph strains, but it is those strains which have been passed repeatedly by dermal inoculation on cows, sheep or rabbits that are considered below, as such strains have been studied most intensively and are best characterized.

Clinical Picture

The infection commonly produced by inoculation of vaccinia virus on human skin has been described above. Occasionally, the illness which follows vaccination is much more severe Secondary lesions may arise elsewhere on the skin through transfer of infection, usually by the fingers, from the initial lesion at the site of inoculation. But more generalized infection is sometimes seen, and this may present 1 of 3 distinct clinical pictures: eczema vaccinatum, true generalized vaccinia and progressive vaccinia (vaccinia gangrenosa)

Eczema vaccinatum may occur as a complication of vaccination in children, or occasionally in adults, who suffer from chronic dermatitis. But in some instances the infection is acquired by unvaccinated children through contact with a recently vaccinated person Groups of cases have occurred in dermatologic wards in hospital (Sommerville et al, 1951). In these patients there may be a febrile illness before the appearance of the eruption. Vesicles appear rapidly and are usually umbilicated. The lesions occur for the most part on areas of skin subject to eczema, although it may not extend to all such areas, and vesicles may appear in previously healthy skin. There is usually adenitis of regional lymph nodes, and high fever is common. The condition may be clinically indistinguishable from eczema herpeticum in which the causal

readily in stained preparations with the ordinary light microscope or in unstained preparations by darkground illumination or by phase-contrast microscopy, as small spherical bodies of approximately 0 2 μ in size. Estimates of size obtained by ultrafiltration through gradocol membranes by Andrewes and Elford (1932) were rather less (0 125 to 0 175 μ) The figures calculated from ultracentrifugation data have varied in the range from 125 to 252 mμ. Measurement of particles in electronmicrographs gives values about 230 to 300 mμ The density of elementary bodies has been determined by the sedimentation rate of the particles in fluids of different specific gravity Because of different osmotic effects exerted by the suspending fluids used—urea, glycerol and sucrose—the density of the virus has been found to vary between that of bacteria 1 10 and that of proteins 1 33

Electronmicroscopy has contributed much to our knowledge of the size and the structure of vaccinia virus The observations made by Green et al (1942) on dried films of elementary bodies indicated that the virus under these conditions was brick-shaped and contained a central area more opaque to the electron beam Short treatment with 0 02 N NaOH increased the prominence of the central area Extraction with 0 1 N NaOH laked the particles, leaving empty ghosts Treatment of elementary bodies with crystalline pepsin dissolved three quarters of the virus substance but left the central body, 90 mμ in diameter, apparently unaltered (Dawson and McFarlane, 1948), all the phosphorus and the desoxyribonucleic acid remained in the residue Incubation with desoxyribonuclease liberated the nucleic acid in soluble form with some loss of density of the central body In preparations from infected chorio-allantois or rabbit cornea electronmicrographs revealed a greater variation in size of elementary bodies (240 to 380 mμ × 170 to 270 mμ) than that seen in preparations from purified suspensions (Peters and Nasemann, 1952) The results of enzymatic digestion varied with the method of fixation, but after Chabaud fixation and treatment with pepsin many of the elementary bodies showed well-differentiated outer membrane and central body Treatment with desoxyribonuclease did not remove the inner body but so altered it that further treatment with pepsin left membranes empty (Stoeckinius and Peters, 1955). The inner body appears to be composed of desoxyribonucleoprotein, and the appearances seen after various enzymatic treatments were similar to those observed in preparation of *E. coli* and *Neisseria sicca* (Peters and Stoeckinius, 1954) The electronmicroscopic examination of thin sections of vaccinia-infected tissue have served to show the relation of intra-cellular virus to other cell constituents (Wyckoff, 1951), although with this technic the problems of artefact production are considerable. The virus particles all appear oval or round but vary in size, density and inner structure (Gaylord and Melnick, 1953). Many particles had incomplete membranes and before release from the cell often showed a double membrane (Morgan et al, 1954) In the absence of sequential studies, correlated with biologic observation, the interpretation of these findings in relation to a developmental cycle of the virus must remain conjectural

The virus of vaccinia has a complex chemical structure Protein, nucleic acid (DNA), phospholipid, neutral fat and carbohydrate have been found in purified elementary body suspensions in amounts similar to those of bacteria and mammalian cells Chemical analysis of purified elementary bodies showed the following percentage composition in dry weight carbon 33 7, nitrogen 15 3, phosphorus 0 57, copper 0 05, total lipids 5 7 (consisting of cholesterol 1 4, phospholipid 2 2 and neutral fat 2 2), reducing sugars 2 8, thymonucleic acid 5 6 (Smadel, 1952) Of these cholesterol could be removed by ether extraction without altering the infectivity of the preparations Practically all the phosphorus and the reducing sugars are contained in the thymonucleic acid fraction Vaccinia elementary bodies also contain biotin and flavin Phosphatase, catalase and lipase activity have been found in suspensions of elementary bodies, but it is uncertain whether these enzymes are integral constituents of the virus and not adsorbed from the host cells Some information as to the probable distribution of genetic material in the vaccinia elementary body is available from the observations of Lea and Salaman (1942) As a result of studies on the inactivation of virus by exposure to alpha rays, x-rays and gamma

tories or institutes vary in their effects on animals The method of routine propagation of these strains may determine the greater tendency of some to induce fatal encephalitis on injection into rabbits (Herzberg, 1955) The strains examined by Herrlich and Mayr (1954) showed fairly constant differences in the nature of the lesions produced in the rabbit skin and on the chorio-allantois, and similar differences have been noted by Fenner (1958) The strains that have been repeatedly passed by scarification on the skin of calves or rabbits—dermal strains—tend to be less virulent for animals than those propagated by repeated passage in the rabbit testis—testicular strains—or in the rabbit brain—*neurovaccinia* The lesions produced by dermal strains in the rabbit skin and on the chorio-allantois tend to be less hemorrhagic than those produced by testicular virus or neurovaccinia These latter strains have a greater ability to grow in mesodermal tissues Strains with high virulence for mice may arise similarly by repeated intracerebral passage in these animals or by frequent intraperitoneal passage in mice with ascites tumors (Cassel, 1957) As previously noted, repeated propagation of vaccinia strains on the chorio-allantois or in chick embryo tissue culture tends to lessen the virulence of vaccinia virus for the rabbit and for man In tissue cultures using HeLa cells cytopathogenic effects may be visible within 48 hours (Ryden and Randall, 1957) It is apparent that the results of experimental infection in different animal species will be determined, among other things, by the history and the properties of the particular strain of virus under study A more detailed account of the effects of vaccinia virus strains on experimental animals has been given by van Rooyen and Rhodes (1948).

Etiology

The virus of vaccinia was probably first seen and depicted by Buist in 1887 (Gordon 1937). This publication was overlooked, and elementary bodies were described by Paschen in 1906 who found them regularly in material from vaccine pustules and in the lesions of smallpox and observed that they were agglutinated by immune sera (Paschen, 1924). The association of infectivity with the elementary bodies was established by centrifugation experiments on Berkefeld filtrates of rabbit dermal pulp extracts (Eagles and Ledingham, 1932) and by studies with collodion membrane filters of graded porosity (Elford and Andrewes, 1932). Perhaps the final proof that the elementary bodies of vaccinia are the virus came from experiments designed to show that lesions could be produced by single elementary bodies (Parker and Rivers, 1936a; Smadel, Rivers and Pickels, 1939). The ratio of virus particles to infective units in such experiments obviously depends on the virulence and the viability of the particles and the susceptibility of the tissue used to determine infectivity, but the fact that the ratio approached unity is also good evidence for believing that the elementary body is the virus. The ratios of particle count to infective units of vaccinia virus have been reinvestigated recently by Overmann and Tamm (1956) and Dumbell et al. (1957), using improved technics of counting virus particles by the electronmicroscope (see Chap. 2).

Vaccinia virus was propagated in laboratory animals for the production of smallpox vaccine many years before its nature was established It was also the first virus to be prepared in a relatively pure state in quantities which permitted detailed examination of its physical, chemical and antigenic structure The preparation of purified suspensions involves the separation of virus from the tissue cells in which it has multiplied. The technics commonly used are based on that of Craigie (1932) who improved on the methods of earlier workers The starting material is the infected epidermis of rabbits that have been inoculated 3 or 4 days before by rubbing into the skin a concentrated suspension of rabbit adapted virus Suspensions of virus may be obtained in the same way from the skin of the sheep or the calf The infected chorio-allantois may also serve for the preparation of virus suspensions by a similar technic, although it is more difficult to free such suspensions from tissue particles (Smadel and Wall, 1937).

A comprehensive account of the properties of vaccinia virus is given in the 2nd edition of this book by Smadel (1952), who with Rivers and their colleagues, have contributed much to our knowledge of the elementary body of vaccinia virus. The virus can be seen

60° C., whereas the S antigen is stable on heating to 90° C. or even higher. This soluble antigen can be concentrated by iso-electric precipitation (Craigie and Wishart, 1936b) and when purified has been found to possess the properties of a protein molecule with molecular weight 240,000 (Smadel and Shedlovsky, 1942). It appears that this protein has 2 antigenic groupings which elicit distinct antibodies. The L and S parts of the antigen can be degraded independently by appropriate treatment (Smadel, 1952). Mayr et al. (1955) in their studies of soluble antigen from various pox viruses could find no evidence of a labile fraction in purified preparations, but it is doubtful if their serologic technics were suitable for the demonstration of the labile moiety of the antigen.

The nucleoprotein antigen is also a serologically specific component of the vaccinia virus (Smadel et al., 1942). It is obtained by extraction of elementary bodies with dilute alkali and constitutes at least half the substance of the virus. It contains 6 per cent thymonucleic acid and precipitates and fixes complement with antivaccinial serum. Injection of noninfectious alkaline extracts of elementary bodies elicits precipitins in rabbits, but such animals are not immune to infection, nor do their sera contain neutralizing antibody.

The LS and NP antigens make up a considerable proportion of the surface of elementary bodies, and these are agglutinated by LS and NP antibodies. After absorption of hyperimmune sera with LS and NP antigen so that the serum no longer precipitates with these antigens, elementary bodies are still agglutinated, although to a lower titer than with unabsorbed sera (Smadel and Shedlovsky, 1942). This residual agglutinin has been designated X agglutinin. Its relation to other antibodies in antivaccinial serum remains undetermined. Vaccinial hemagglutinin (Nagler, 1942) is active against the red cells of only some fowls. The hemagglutinin can be freed from the virus particle by centrifugation, and virus preparations of undiminished infectivity can be obtained by absorbing out the hemagglutinin with suitable red cells (Burnet and Stone, 1946). The hemagglutinin was found by filtration experiments to be a relatively large particle, i.e., 65 mμ (Chu, 1948), although Gillen et al. (1950) thought that there were 2 components—a larger heat stable and a smaller heat labile fraction. Briody (1951) has suggested on the basis of results of treatment with trypsin and ethyl alcohol that the hemagglutinin is polydisperse. It is probably a lipoprotein with phospholipid as the lipid component (Burnet and Stone, 1946). Antibodies to hemagglutinin appear in the serum after vaccinial infection of man or animals, but the antibody is not related to LS or neutralizing antibody. The hemagglutinin of vaccinia is very similar to that produced by variola virus on the chorio-allantois (North, 1944). The antibodies corresponding to LS, NP and hemagglutinating antigens are apparently distinct from the neutralizing antibody present in immune sera. Injection of these separate antigens do not induce immunity or the formation of neutralizing antibody in rabbits, absorption of immune sera by these antigens fails to remove neutralizing antibody. However, absorption of immune sera with appropriate amounts of active elementary bodies removes not only agglutinins and precipitins (LS and NP antibodies) but also neutralizing antibodies (Salaman, 1937). It seems that the antigen associated with the living particle which determines the production of immunity and neutralizing antibody after infection is relatively labile, but its nature is unknown.

The immunologic relationship of cowpox and smallpox was established by Jenner when he showed that individuals recovered from cowpox infection could not be variolated successfully. His observations were confirmed repeatedly by other physicians within a few years of the publication of his findings. Similarly, the immunity induced in man by smallpox against vaccinia has been established by the fact that, after the appearance of the eruption of smallpox, vaccination fails to take (Ricketts and Byles, 1908, Marsden, 1948). The serum of recently vaccinated individuals neutralizes the virus of smallpox when tests are made on the chick embryo chorio-allantois (Buddingh, 1943), and convalescent serum from alastrim patients neutralizes the viruses of vaccinia, cowpox and variola when tested in the same way (McCarthy and Downie 1953). The soluble antigens from tissues infected with variola, vaccinia, cow-

rays, they concluded that vaccinia is a complex of genes and genetically inert material, and that the genes are either dispersed through the particle or confined to a nucleus of a diameter at least half that of the particle The internal structure of the virus as revealed by electronmicroscopy and the amount of nucleoprotein determined by chemical analysis are compatible with the conclusions of Lea and Salaman (1942).

The virus of vaccinia is relatively stable. It may be kept almost indefinitely when stored at $-70°$ C in suitable suspending fluid and will remain active in sealed ampules at ordinary refrigerator temperatures for many months. The virus withstands drying, and when freeze-dried and kept in an atmosphere of nitrogen, preparations maintain their activity for years In fluid suspension vaccinia is destroyed by heat at 60° C for 10 minutes but in dry form withstands 100° C. for 10 minutes Ultraviolet light, alpha rays, x-rays and gamma rays all have a rapidly lethal effect, and the virus is sensitive to the photodynamic action of various dyes in the presence of light (van Rooyen and Rhodes, 1948) The virus in vaccine lymph containing 50 per cent glycerol survives for months at 4° C and at $-10°$ C. may remain active for years Many reports have appeared on the effect of various chemical substances on vaccinia virus, but the results vary with the nature and the reaction of the suspending medium, the amount of protective protein present and the temperature at which tests are made The virus loses activity at pH 3 0 within an hour It withstands the action of 1.0 per cent phenol for weeks at 4° C. but at 37° C may be inactivated in 24 hours It is not destroyed by certain disinfectants in concentrations which are rapidly lethal to most bacteria, e g, 1:10,000 brilliant green, but is inactivated by oxidizing disinfectants, e g, potassium permanganate 1·10,000 Alcohol, methyl alcohol and acetone in 50 per cent concentration inactivate vaccine lymph within 1 hour Vaccinia is more resistant to the action of ethyl ether than many other viruses Many substances have been tested for chemotherapeutic effect in vaccinial infected animals, but spectacular results have not been achieved (Chap 6).

Animals which have recovered from infection with vaccinia virus are resistant to further infection, and their sera will confer passive protection on normal animals against vaccinia virus The antibodies in the serum of immune animals may be increased by further injections of virus, and for the preparation of hyperimmune sera in rabbits purified suspensions of active elementary bodies may be injected intravenously. Injection of virus inactivated by heat or formalin into normal animals produces a relatively low degree of immunity to infection, and the sera of such animals has little protective or neutralizing effect on the virus (Parker and Rivers, 1936b) Inoculation of relatively large doses of purified virus inactivated by ultraviolet light produces a rather greater degree of immunity but is inferior to active virus as an immunizing agent (Collier et al, 1955) The sera of immune animals can be shown by various in vitro technics to react with virus preparations, indeed, precipitation and complement-fixation reactions were demonstrated many years ago (Smadel, 1952) By studies with purified suspensions of elementary bodies a picture of the antigenic structure of vaccinia has been built up as detailed as that available for many bacteria The following antigens have been recognized, LS or soluble antigen, NP or nucleoprotein antigen and a hemagglutinin In addition to the antibodies which react in vitro with these antigens, antivaccinial sera contains other antibodies which are considered below.

The LS antigen of vaccinia may be obtained free from virus in extracts of vaccinia-infected tissue and forms part of the surface of elementary bodies from which it slowly dissociates when purified elementary body suspensions are kept at refrigerator temperature The LS antigen flocculates and fixes complement when mixed with antivaccinial serum The agglutination of elementary bodies with specific antiserum is due, in part at least, to the presence of this antigen at the surface of the virus particles. Injections of LS antigen into rabbits stimulates antibody formation which reacts with the antigen in vitro, but the animals are not thereby immunized against infection with vaccinia virus nor do their sera contain neutralizing antibodies The L part of the antigen is inactivated by heating at

sence of antibody response, had a normal amount of gamma globulin in his serum The agammaglobulinemic infant suffering from progressive vaccinia recorded by Lewis and Johnson (1957) died, although large doses of immune gamma globulin had been given

Epidemiology

Accidental infection with vaccinia may occur in persons working in laboratories where the virus is being studied, and infection may be contracted through contact with a recently vaccinated person This is particularly liable to happen to individuals suffering from chronic dermatitis

Control Measures

Persons who propose to work with vaccinia should be vaccinated or revaccinated before beginning such work Children suffering from any form of chronic dermatitis should be protected from contact with recently vaccinated persons, where such exposure has occurred or when vaccination of such children has to be carried out because of the risk of exposure to smallpox, serious complications may be avoided by the administration of 0 6 ml of hyperimmune vaccinal gamma globulin per Kg body weight (Kempe et al, 1956)

pox and ectromelia show serologic similarity when cross-tested by the complement-fixation or inhibition of complement-fixation technics with immune sera prepared in rabbits or fowls (Downie and Macdonald, 1950) By neutralization tests with such sera on the chorio-allantois, the viruses of alastrim and variola could not be distinguished, and the immunologic differences between them and vaccinia, cowpox and ectromelia were no greater than the differences observed between some strains of influenza A virus (Downie and McCarthy, 1950).

Many substances have been tested for possible chemotherapeutic effect on vaccinia virus. Screening tests have usually been made for inhibitory effect on the growth of vaccinia virus in tissue culture or on infections of the chick embryo, mice or rabbits. Results have varied according to the technic used, so that a substance which may inhibit the virus in tissue culture may not influence the progress of infection in the chick embryo or the mouse. Sulfonamides and the antibiotics have generally little inhibitory effect. In the hope of interfering with the synthesis of virus nucleic acid or virus protein, analogues of purines, pyrimidines and amino acids have been examined Structural analogues of purine and pyrimidine bases may inhibit the growth of virus in tissue culture. Certain 5 phenoxy thiouracils, although only slightly inhibitory to vaccinia virus in the chick embryo, were found to have significant protective effect in mice (Thompson et al, 1951). Thiosemicarbazones also are reported to have some inhibitory activity in mice (Hamre et al, 1951; Bauer, 1955) and a series of benzimidazole derivatives suppressed vaccinial infection in the chorio-allantois in vitro (Tamm and Overman, 1957) The selective activity of different benzimidazole derivatives on vaccinia and influenza viruses appeared to be related to the different kind of nucleic acid in these 2 viruses None of these substances or any others tested so far seems to hold out any immediate prospect of practical application as therapeutic agents in diseases due to pox viruses. Recent reviews of this field are to be found in the paper of Horsfall and Tamm (1957) and in Chapter 6.

The growth of vaccinia virus has been followed in tissue culture, in the chick embryo, in the mouse and in the rabbit. Generally it has been found that increase of virus is first detectable after 8 to 16 hours from the time of inoculation, and thereafter there appears to be a logarithmic increase for the next 24 to 36 hours A variable decrease in infectivity has usually been noted during the first 8 to 10 hours after inoculation—the latent period On analogy with what has been observed with phage and reported also in the case of influenza virus, it has been suggested that vaccinia virus passes through a noninfective phase early in its intracellular development before mature particles are formed. Although some observers have reported an almost complete disappearance of infective virus during the first few hours, in the experiments of Overman and Tamm (1957) and of Maitland and Magrath (1957) the drop in infectivity amounted to only 50 per cent. In work of this kind the apparent loss of virus may be due to imperfection of methods for extracting infective virus from the tissues under examination. Although many of the reported studies on the eclipse phase support the view that there is an intracellular noninfective stage in the development of vaccinia virus, further work is desirable, perhaps with improved cell culture technics, before this view of the mode of growth of vaccinia virus could be generally accepted

Diagnosis

The diagnosis of the generalized forms of vaccinia will usually be made on the history of recent vaccination or contact with a recently vaccinated person and the character of the cutaneous lesions Where laboratory confirmation is required as, for example, for differential diagnosis of eczema herpeticum and eczema vaccinatum, the laboratory procedures outlined in the section on diagnosis of variola are applicable.

Treatment

In cases of generalized vaccinia where the immunologic response to infection may be deficient, hyperimmune vaccinal gamma globulin may be of value (Kempe et al, 1956). Of the cases of progressive generalized vaccinia recorded, the only one which recovered received 5 injections of immune gamma globulin over a period of 6 weeks (Barbero et al, 1955). But this patient, in spite of the ab-

Psittacosis—Lymphogranuloma Venereum Group

INTRODUCTION

These large intracellular parasites (1) responsible for diverse, natural, clinical and latent infections in birds, man and other mammals, (2) readily stained by basophilic dyes, (3) antigenically related, according to complement fixation, cross immunity and toxin neutralization tests, (4) producing pneumonitis in the laboratory mouse when introduced by the intranasal route, (5) growing well in the yolk sac of the embryonated egg and (6) susceptible to the action of certain chemotherapeutic agents form a distinct biologic group. Since the basic group characteristics were first recognized in the agent responsible for psittacosis and several years later in that of lymphogranuloma venereum, the group is called the psittacosis-lymphogranuloma venereum group. It is composed of a large, increasing number of similar infectious agents whose nature and relationship to other micro-organisms is still imperfectly understood. In susceptibility to sulfonamides, penicillin, tetracycline and other chemotherapeutic agents they resemble the bacteria, in their strictly intracellular multiplication with cytoplasmic inclusion bodies and in their relationship to the metabolism of animal cells they behave more like true viruses than like rickettsiae. Some of their morphologic and antigenic properties relate them to the newly created group of Neorickettsiae (Philip et al., 1953, Philip, 1955, Giroud and Jadin, 1954, Giroud et al., 1955, Giroud, 1956). They lie along an indistinct line that separates virus from not virus. It is too soon to follow the taxonomy proposed by Moshkovsky, 1945, who suggested the family name *Chlamydozoaceae* and the genus name *Miyagawanella*. The group is now categorized on the basis of host-parasite relationships; the ultimate classification probably will be based on antigenic characteristics. Since Bedson (1936) made the first comprehensive study of a member of this group, including identification of 2 antigens of the psittacosis agent, it may be appropriate to consider *Bedsonia* as the name of the genus, at least for all of the parasites now called psittacosis viruses of avian, human and mammalian origin (Meyer, 1953). If the serologically related viruses were to be placed in a single genus, then the 8 species given in Bergey's *Manual* require redistribution.

For nearly 10 years after the first isolation of psittacosis virus from parrots and patients in 1930 it was believed that *Psittaciformes* imported from their natural tropical habitat or raised by hobbyists or commercially in the United States and Europe were the only sources of the virus. Then fulmars, or petrels, were found to be sources of hu-

PSITTACOSIS

(SYNONYMS: Parrot fever, ornithosis, *psittacose*, *Papageienkrankheit*)

INTRODUCTION

In his thesis, *De la psittacose ou infection spéciale déterminée par des perruches*, Antonin Morange introduced the name psittacosis for a clinically defined disease of man caused by parrots, and because of its appropriateness to what was then known of the infection, this term found wide usage When it was recognized that a great variety of birds are affected by this virus, the more general term "ornithosis" was introduced The word "psittacosis' refers to a generalized viral infection of man derived from birds, among which parrots, parakeets, lovebirds, ducks pigeons and turkeys are important sources, and to the infections caused naturally by the same agents in psittacine birds Ornithosis regarded as an equivalent term in the sixth revision of the *International List of Diseases and Causes of Death* and as a synonym in the eighth edition of *Control of Communicable Diseases in Man* (1955), is reserved for infections of similar etiology in extrapsittacine birds

The human illness may be severe carrying a high mortality rate, or it may be mild or even subclinical It affects all ages and both sexes Its cause is an elementary body virus that develops in reticuloendothelial cells

HISTORY

From a relatively obscure disease first recognized in Switzerland, then in France and Germany, psittacosis became the subject of world-wide interest in 1929 and 1930 when outbreaks occurred in 12 countries and involved about 800 people Careful inquiries by Roubakine, 1930, and by Barros, 1940, indicate that parrots shipped out from South America were the main source of the infection (Meyer, 1942, Van Rooyen 1955) The eventual isolation of the agent from parakeets, pigeons, doves, chickens, ducks, seagulls, turkeys and other birds (Meyer and Eddie, 1952) has well established that there were sources of this infection independent of imported exotic birds Levinthal, Coles and Lillie in 1930 simultaneously discovered the minute spherical bodies within reticuloendothelial cells, and Bedson and Bland (1932) conclusively proved the etiologic relationship of the elementary bodies to infection Propagation of the virus in embryonated eggs and tissue cultures has furnished suitable antigens for serologic studies, and methods of isolating the viral agent from the sputum and the blood of psittacosis patients have been developed Procedures for measuring anti-infectious and toxin-neutralizing properties have revealed the antigenic relationship of strains isolated from birds and mammals. Wide-spectrum antimicrobial drugs tested experimentally and clinically have reduced the case fatality rate in man and have furnished promising evidence that chemotherapy may be used to render psittacine birds noninfectious (Cox, 1955)

CLINICAL PICTURE

The clinical form characterized by pneumonic consolidation and a mortality rate of 20 per cent was the first to be described in the classic accounts of the French clinicians, but now it is known that the severity varies within wide limits Serologic studies indicate that subclinical infections occur, and because of their similarity to common respiratory disease it is fairly certain that mild, atypical and ambulatory infections often go unrecognized Moderately severe, severe and fatal infections are in all probability less frequent but they are more commonly diagnosed because their cause is sought The duration of the illness may be short, terminating abruptly, or it may pursue a low-grade course over 3 months.

After an incubation time of 1 or 2 weeks, occasionally 3 or 4 weeks, the onset may be sudden with chilly sensations, fever, anorexia sore throat, malaise, photophobia and severe headache, or it may be gradual and insidious. The temperature at the onset is usually from 100° to 102° F and gradually rises During the second week in severe cases it remains high with slight morning remissions; in mild cases it may fall to normal on the 7th or 8th day. The pyrexia subsides by lysis

On physical examination of the thorax, moist rales in the absence of consolidation is the most characteristic finding It is not unusual, however, that there are no abnormal findings or that there is consolidation. The extent of the pneumonitis is usually not evi-

man infections on the Faeroe Islands In that year lymphogranuloma venereum found its place in the psittacosis group when the large elementary bodies in mononuclear cells of tissues were obtained from afflicted human beings, grew in the embryonated chicken egg and revealed a developmental cycle very similar to that of psittacosis The study of certain forms of pneumonia in human beings and of the lungs or other tissues of healthy or diseased mammals soon led to the discovery of viral agents not readily distinguishable from those causing psittacosis Not only are viruses of this group being recognized as the cause of disease in a growing number of mammals, but also similar infections are being found in many extrapsittacine species. The epidemiologic problems are multiplying accordingly. Little is yet known about the mammalian viruses or about their incidence in domestic animals or man They have caused significant economic losses of domestic herbivores Widespread latent infections in wild and domestic pigeons and barnyard fowl such as chickens, ducks and particularly turkeys, correctly designated ornithosis, can serve as reservoirs for serious and fatal "zoo-anthroponosis." Epizootics induced by vigorous, virulent strains impose heavy direct and indirect losses on the poultry industry

The psittacosis-lymphogranuloma venereum agents isolated during the past 20 years, grouped according to their host, are

1. **Avian Viruses.** Psittacosis virus (Coles, 1930, Levinthal, 1930, Lillie, 1930), ornithosis viruses including fulmar virus (Haagen and Mauer, 1938), pigeon and dove virus (Coles, 1940, Meyer and Eddie, 1941),

wycz et al, 1955), pheasant virus (Meyer and Eddie, 1956b)

sum viruses A and B (... 1949), bovine enteritis (York and Baker, 1956), bovine encephalomyelitis virus (Menges et al, 1953), enzootic abortion of ewes virus (Stamp et al, 1950; Barwell and Bishop, 1951), pneumonitis of sheep (McKercher, 1952), pneumonitis of goats (Omori et al, 1953), bovine pneumonia virus (Matumoto et al, 1955).

3. **Human Pneumonitis Viruses:** The high person-to-person communicability is the basis of the idea that the San Francisco (S F.) virus (Eaton et al., 1941), Louisiana (Borg) virus (Olson and Treuting, 1944), Chicago virus (Zichis and Shaughnessy, 1945) and pneumonitis virus (Yeatman and McEwin, 1945; de Gara and Furth, 1948) are specifically human strains

The host-parasite relationship of the viruses of this group is founded in the unique biologic characteristic of residual quiescent infection or latency first demonstrated in birds, then mammals (e g, mice, cattle, sheep and goats) and finally in man As a rule, infection takes place in young birds and mammals. The mortality rates vary; epizootics sometimes occur in poultry flocks and aviaries, but in the natural habitat of wild birds they are exceptional A stable association of host and parasite appropriate for survival of both is recovery of the host followed by long-lasting subclinical infection, providing the parasite ample opportunity to infect other hosts but having virtually no deleterious effect on the host. When an epizootic leads to the death of a large proportion of hosts a breakdown in this established equilibrium has taken place The virus may infect some new susceptible species brought into its environment, or a virus of higher virulence may emerge as a result of repeated transfer through fully susceptible hosts. In a proportion of the infected, after benign illness inapparent infection persists; the virus present in reticuloendothelial cells may be confined indefinitely to the viscera, or it may spill over and leave the infected hosts in excreta ... able percentage of the in- ... vi- ... ues ... ost- ... va-

tion, crowding, low temperature, illness, possibly hormonal factors (Austin, 1957), the virus may multiply beyond the capacity of the fragile immunity and thus be released into the environment. The large reservoirs of virus in birds and mammals in nature are usually self-confined, but under conditions frequently not clearly understood the overflow of the infective agent endangers the health and the welfare of other hosts, including man.

exudate and the minor change in the large bronchioles and bronchi give the pneumonia in psittacosis a fairly characteristic, but not pathognomonic, pattern. In some cases the lesions are similar to those in interstitial pneumonia associated with other viruses. Binford and Hauser (1944) distinguished between the microscopic lung lesions of psittacosis and those of Q fever and other virus pneumonias.

In the slightly enlarged and congested liver, the characteristic microscopic lesions are due to focal necrosis. Kupffer cells contain elementary bodies. The spleen may or may not be enlarged and may contain relatively small follicles and engorged sinuses filled with phagocytic cells. Cloudy swelling, hypertrophy of the cardiac muscle, interstitial edema, infiltration with plasma cells, and lymphocytes and subendocardial hemorrhages in the region of the mitral, the aortic and the bicuspid valves have been reported. The parenchyma of the kidneys may be degenerated. Hemorrhages and capillary thrombi have been observed in the adrenals of patients infected with the highly toxic Louisiana virus and in the glomerular capillary tufts of the frontal lobes of the brain (Prouty and Jordan, 1956). Congestion and edema of the brain and the spinal cord are not infrequent. Chromatolysis in the anterior horn cells, glia proliferation, occasional changes in the ganglion and proliferative degenerative changes in the capillary endothelium are attributable to toxic factors primary or secondary to pneumonia. In the rare cases of meningitis intracytoplasmic inclusions have been identified in the gelatinous exudate over the pia arachnoid (Walton, 1954).

Two observations have been made early in experimental infection that may explain the pathogenicity of the elementary bodies. In murine pneumonitis of mice following aerosol exposure, throughout the development of the elementary bodies to vesicles no inflammatory reaction could be discerned in the alveoli. But when the vesicles burst, probably releasing toxin or host cell components, polymorphonuclear cells accumulated in the alveoli, lung macrophages were mobilized, and phagocytes poured out from the capillaries into the alveoli. The intense cellular infiltration interfered with further vesicle formation, and virus proliferation was never most active in the center of the inflammatory foci. When infection leads to complete consolidation of the lungs, death results from suffocation. The injury by murine pneumonitis virus is relatively direct and causes a nonspecific reaction in the host (Gogolak, 1953).

Experimental Infection, Host Range

Members of this group vary considerably in their affinity for tissue cells and hosts. The most virulent psittacosis and turkey ornithosis strains for man have the broadest range of host and tissue pathogenicity. They are followed in decreasing breadth of range by ornithosis strains isolated from pigeons and ducks, by meningopneumonitis, feline and mouse pneumonitis and other mammalian strains.

Mice, the most useful indicator animals, may be infected by the intranasal, intraperitoneal, intracerebral, intravenous or subcutaneous routes or by feeding, depending on the viral isolates used. They are of little value in isolating virus from cattle or goats. The duration of the illness depends on the amount, the virulence and the toxin-producing ability of the virus. Intravenous and intraperitoneal titrations in mice of isolates from birds have given useful information about their virulence. Repeated titrations reveal differences between log ID_{50} and LD_{50}, and these may be used to calculate a pathogenicity index. As the lethality titer approaches equivalence with the infectivity titer, the index approaches 0. A low index indicates high mouse pathogenicity, and a high index (i.e., 4) indicates an infectivity 10,000 times greater than the lethality. In general, isolates from severe human infections, parrots, parakeets and turkeys involved in human outbreaks have yielded a low index. Strains from pigeons and ducks and from sporadic infections in turkeys have yielded high indices.

Death ensues in 2 to 6 days for the highly virulent and in 8 to 15 days for the low virulent strains, some mice recover. In animals infected orally or subcutaneously the course is always protracted. Latent infections have persisted for 10 to 12 months. The virus has been isolated from mice treated with antimicrobial drugs as long as 277 days after inoculation (Hurst et al., 1953). At necropsy 2 to 4 days after intraperitoneal inoculation the spleen and the liver look normal, but the abdominal viscera are covered by a thin, sticky exudate consisting of endothelial cells

dent until roentgenologic examination, which shows infiltration. This may be patchy over *one or both lungs, but it is usually broncho*pneumonic. Physical signs begin to subside by the third week, but roentgenograms disclose a slower resolution. Pleural reaction is generally slight or absent. During the first few days a slight irritating cough may persist or increase, or, despite extensive lung involvement, cough may be insignificant or ab*sent throughout the entire illness. There is* usually no excess of sputum; in some cases it may be at first mucoid and later mucopurulent. The rate and the depth of respirations are not increased except in fatal cases, in which a rate as high as 60 per minute has been observed.

The relative slowness of the pulse is characteristic, but in nearly all fatal cases the pulse becomes rapid and weak. Cyanosis and low blood pressure may be marked; collapse *sometime during the illness is common. The* cardiovascular system is altered in many cases. Myocardial involvement, which may extend far into convalescence, is being observed oftener since electrocardiograms are more common (Lyon, 1956, Kemmerer et al, 1956) Epistaxis and rose spots are considered signs of general vascular damage. Thrombophlebitis *may occur and cause death* through pulmonary embolism (Jørgensen and Steffensen, 1956).

*Severe psittacosis shows the greatest vari*ability in clinical features. Nausea and vomiting are common, and either constipation or diarrhea may be present. *Albuminuria is not* infrequent. In some patients organs and sys*tems other than the lungs are involved.* Hepatosplenomegaly, even acute thyroiditis, have been reported (Seibert et al., 1956). Jaundice and oliguria have been noted (Yow et al., 1957). The spleen may be enlarged temporarily, but in most cases it is not palpable (Meyer, 1954). The leukocyte count is either normal or subnormal, with eosinopenia; leukopenia is pronounced in only about 25 per cent of the cases. Leukocytosis occurs late in the disease or in early convalescence. Psittacosis, if treated early and for at least *10 days, seems to run a smooth course,* and circulatory complications are exceptional. Inadequate treatment with respect both to dosage and to time *greatly favors relapses and* slow convalescence. Meningitis, encephalitic symptoms, insomnia, disorientation, apathy, mental depression and even delirium may occur in all except mild infections. In the terminal stages death generally results from pulmonary insufficiency and generalized toxemia.

Until quite recently clinical evidence of in*fection in children was considered unusual.* But in family outbreaks sometimes the children in intimate contact with infective material, such as feathers and droppings, while fondling parakeets or cleaning cages, have become ill or have had no symptoms but developed antibodies (Strobel, 1954; Lippelt and Brand, 1955; Babudieri and Cerri, 1956; *Prouty and Jordan, 1956). In Israel infants* from 1 month to 2½ years old contracted psittacosis. In 6 cases an ornithosis virus was isolated from infants with respiratory symptoms (Ephrati-Elizur and Bernkopf, 1956); 2 cases were fatal, 2 patients suffered moderate to severe respiratory disease, others had only a mild respiratory infection (Berman *et al., 1955).*

Pathologic Picture

... those of ... n in the ... user, *19*... idly palpable and sharply demarcated from normal lung tissue. They are gray, gray-red or plum-c... there ... posits. *In the trachea and the ...* cases they are empty, and the mucosa is not swollen. When the psittacotic process is com*plicated by secondary bacterial invasion, the* mucosa is swollen, and the bronchi are filled with purulent exudate. Microscopic examina*tion discloses that the portions that* had looked completely consolidated have undergone unevenly distributed lobular changes *Alveoli containing air or serum are dispersed* throughout the consolidated portion In fully developed lesions the alveolar spaces contain *abundant fibrin and many lymphocytes,* macrophages and desquamated alveolar epithelial cells Many cells in the alveolar exudate and *in the lymph sinuses of the hilar lymph nodes* show evidence of active phagocytosis and intracytoplasmic elementary bodies The scarcity of polymorphonuclear leukocytes in the

exudate and the minor change in the large bronchioles and bronchi give the pneumonia in psittacosis a fairly characteristic, but not pathognomonic, pattern In some cases the lesions are similar to those in interstitial pneumonia associated with other viruses Binford and Hauser (1944) distinguished between the microscopic lung lesions of psittacosis and those of Q fever and other virus pneumonias

In the slightly enlarged and congested liver, the characteristic microscopic lesions are due to focal necrosis Kupffer cells contain elementary bodies The spleen may or may not

the cardiac muscle, interstitial edema, infiltration with plasma cells, and lymphocytes and subendocardial hemorrhages in the region of the mitral, the aortic and the bicuspid valves have been reported The parenchyma of the kidneys may be degenerated Hemorrhages and capillary thrombi have been observed in the adrenals of patients infected with the highly toxic Louisiana virus and in the glomerular capillary tufts of the frontal lobes of the brain (Prouty and Jordan, 1956) Congestion and edema of the brain and the spinal cord are not infrequent Chromatolysis in the anterior horn cells, glia proliferation, occasional changes in the ganglion and proliferative degenerative changes in the capillary endothelium are attributable to toxic factors primary or secondary to pneumonia In the rare cases of meningitis intracytoplasmic inclusions have been identified in the gelatinous exudate over the pia arachnoid (Walton, 1954)

Two observations have been made early in experimental infection that may explain the pathogenicity of the elementary bodies In murine pneumonitis of mice following aerosol exposure, throughout the development of the elementary bodies to vesicles no inflammatory reaction could be discerned in the alveoli But when the vesicles burst, probably releasing toxin or host cell components, polymorphonuclear cells accumulated in the alveoli, lung macrophages were mobilized, and phagocytes poured out from the capillaries into the alveoli The intense cellular infiltration interfered with further vesicle formation, and virus proliferation was never most active in the center of the inflammatory foci When infection leads to complete consolidation of the lungs, death results from suffocation The injury by murine pneumonitis virus is relatively direct and causes a nonspecific reaction in the host (Gogolak, 1953)

Experimental Infection, Host Range

Members of this group vary considerably in their affinity for tissue cells and hosts The most virulent psittacosis and turkey ornithosis strains for man have the broadest range of host and tissue pathogenicity They are followed in decreasing breadth of range by ornithosis strains isolated from pigeons and ducks, by meningopneumonitis, feline and mouse pneumonitis and other mammalian strains

Mice, the most useful indicator animals, may be infected by the intranasal, intraperitoneal, intracerebral, intravenous or subcutaneous routes or by feeding, depending on the viral isolates used They are of little value in isolating virus from cattle or goats The duration of the illness depends on the amount, the virulence and the toxin-producing ability of the virus Intravenous and intraperitoneal titrations in mice of isolates from birds have given useful information about their virulence Repeated titrations reveal differences between log ID_{50} and LD_{50}, and these may be used to calculate a pathogenicity index As the lethality titer approaches equivalence with the infectivity titer, the index approaches 0 A low index indicates high mouse pathogenicity, and a high index (i e , 4) indicates an infectivity 10,000 times greater than the lethality In general, isolates from severe human infections, parrots, parakeets and turkeys involved in human outbreaks have yielded a low index Strains from pigeons and ducks and from sporadic infections in turkeys have yielded high indices

Death ensues in 2 to 6 days for the highly virulent and in 8 to 15 days for the low virulent strains, some mice recover In animals infected orally or subcutaneously the course is always protracted Latent infections have persisted for 10 to 12 months. The virus has been isolated from mice treated with antimicrobial drugs as long as 277 days after inoculation (Hurst et al , 1953) At necropsy 2 to 4 days after intraperitoneal inoculation the spleen and the liver look normal, but the abdominal viscera are covered by a thin, sticky exudate consisting of endothelial cells

and leukocytes usually packed with viral bodies There are no lung lesions At necropsy 5 to 10 days after intraperitoneal inoculation the abdominal cavity is filled with a stringy, turbid, fibrinous exudate, rich in viral bodies, the enlarged liver and spleen are coated with a thick layer of fibrin, which is easily peeled off Regions of necrosis varying in size and number are present along the margins of the liver

Psittacosis, ornithosis, human pneumonitis, meningopneumonitis, opossum B, hamster pne[illegible]

tion of the lung. Discrete foci of pneumonia are manifested as limiting infective dilutions of virus are approached, the areas are gray, almost translucent, 1 to 3 mm. in diameter After they have been adapted to survival in the mouse, other representatives of the psittacosis group induce fatal pneumonitis. Except for murine pneumonitis, enzootic abortion of ewes, bovine enteric and encephalomyelitis viruses, which cause no symptoms, intracerebral injection of other members of the group causes irritability, ataxia, convulsive seizures and death within 3 to 6 days The meninges are moist and deeply injected Microscopically, the meningo-encephalitis is characterized by an exudate of polymorphonuclear and mononuclear cells, rich in elementary bodies, extending along the blood vessels into the brain This route of artificial infection is useful to increase the amount of virus and to demonstrate quickly the specific viral elements, provided that the material derived from avian sources is free from contaminants and is relatively rich in virus

In guinea pigs most strains produce only a prolonged febrile illness, if that, when inoculated intraperitoneally. But the highly toxic Louisiana pneumonitis, egret, turkey and mammalian (bovine enteritis and encephalomyelitis and pneumonitis of goats and sheep) viruses are highly virulent. The animals succumb to large amounts of virus within 6 to 10 days after a febrile course of 3 or 4 days with temperatures as high as 41 4° C., visible illness, weakness and progressive emaciation At autopsy enlargement of the spleen is usual; a mucoid, viscous, stringy exudate covers the organs, and in a few animals pulmonary consolidation involves one or all lobes of the lungs.

Some strains produce fatal meningo-encephalitis in rabbits infected by the intracerebral route; occasionally, extensive pneumonic consolidations are produced by intratracheal injection Infection of the rabbit's eye has produced a violent reaction. Pocket gophers are susceptible to subcutaneous infection Cotton rats are highly susceptible to the Louisiana virus by the intraperitoneal, intranasal or intracerebral route Wild and white laboratory rats and deer mice are not very susceptible. Syrian hamsters and squirrels (*Citellus beecheyi*) may be fatally infected by the intranasal or intracranial route. *Macacus rhesus* monkeys may be infected by the intratracheal or intracerebral route, psittacosis and highly toxic turkey ornithosis strains produce typical pulmonary lesions or meningo-encephalitis

Parakeets (*Melopsittacus undulatus*), or lovebirds, from aviaries free from psittacosis are susceptible to intramuscular, intranasal and intracerebral infection Immature birds readily contract the infection by exposure to sick birds shedding the virus in droppings When death occurs during the acute stage, gross pathologic findings are a semipurulent coating over the air sac and the inner lining of the sternum, exudate in the pericardial sac, a large liver occasionally studded with areas of necrosis or infarction surrounded by hemorrhagic zones, a large spleen sometimes spotted with necrotic areas, and large, soft kidneys; only rarely are lesions demonstrable in the lungs

With the exception of the meningopneumonitis virus, none of the mammalian viruses is pathogenic for ricebirds, parakeets or pigeons by any route of inoculation, even in very large doses

At least 57 species of the parrot family act as spontaneous hosts to psittacosis (Meyer, 1952). Among 14 different species of the finch family, Java ricebirds (*Munia oryzivora*), canaries (*Serinus canaria*), Poephila, Cyanospiza finches and Java sparrows (*Padda oryzivora*) contract psittacosis when exposed to infected parrots or parakeets.

Domestic fowl (*Gallus gallus*) are susceptible by injection or by exposure; many contract latent infections, and ordinarily few

succumb Pigeons (*Columba livia*) throughout the world are infected; doves (*Streptopelia risoria*), bleeding-heart doves (*Gallicolumba luzonica* and *cruenta*) and Goura pigeons (*Goura cristata* Pallas) (Andrianne, 1953), occasionally infected, are reservoir hosts (Davis, 1955). Pigeons of any breed that have been proved to be free from infection by repeated serologic tests are readily infected by the intramuscular or intracerebral route Intramuscular injections are commonly fatal to doves; intracerebral injections are required to accomplish this result in pigeons Intracranial inoculation of parrot or parakeet psittacosis viruses rarely produces fatal meningo-encephalitis in pigeons, but ornithosis viruses from poultry invariably do so, even in birds with complement-fixing antibodies in their serum

Ducks (*Anas platyrhynchos*) have succumbed to ornithosis during epizootics (Strauss, 1956), or the infection may be clinically inapparent and persist endemically (Korns, 1955). Immature ducks are readily infected by the intramuscular route with any ornithosis virus The disease may end fatally, or after the bird recovers the virus may persist in the liver and the spleen for several weeks, or as long as 1½ months

Indirect evidence that people in the husbandry of pheasant raising may acquire ornithosis has been further supported by isolation of the virus from the spleen of apparently healthy birds (Eddie and Francis, 1942, Ward and Birge, 1952) The pathogenicity of the strains is similar to that of pigeon viruses

Epizootics in commercially raised turkeys have been reported since 1952 from 5 of the United States and British Columbia Undiagnosed flock infections can constitute a serious menace to persons processing anatomically diseased turkeys The viral agent isolated during epizootics resembles the egret and Louisiana strains in its pathogenicity and endotoxin spectrum (Meyer and Eddie, 1953) Clinically inapparent flock infections have yielded isolates of low pathogenicity. The highly virulent strains induce acute, sometimes fatal, infections by intratracheal or aerosol exposure in young turkeys (Pate et al , 1954), isolates of low virulence cause latent infections In Greece serologic surveys have revealed the probability of infection of turkey flocks there (Michail, 1956)

Wild seashore birds, in particular fulmars, petrels, American herring gulls, laughing gull, willet and the mutton bird (Mykytowycz et al , 1955) have been found infected by isolation of the virus Serologic evidence has indicated that other species may be infected (Pollard, 1955) The fulmar and the mutton bird strains have infected man The existence of a reservoir of ornithosis virus in American and nestling snowy egrets has been revealed among birds captured in the coastal areas of Louisiana The virus is pathogenic for mice no matter what route of administration is used (Rubin, 1954)

Etiology

These viruses pass through a relatively complex cycle of development Early studies by Bedson and Bland (1932) working with the psittacosis virus have been extended to the viruses of lymphogranuloma (Rake, 1947), mouse pneumonitis (Karr, 1943), feline pneumonitis (Hamre et al , 1947) and enzootic abortion of ewes (Stamp, 1951) The sequence in the development is fairly uniform After inoculation in mice, embryonated ducks or tissue culture, the elementary bodies disappear The changes that take place in the virus and in the host cell between the disappearance of the elementary body and the appearance of the initial body are incompletely understood This latent period may represent a resting phase, analogous to the lag phase during bacterial growth, in which fully infectious units of virus have penetrated a host cell but have temporarily exhausted the supply of some constituent required for rapid multiplication (Bedson and Gostling, 1954, Weiss, 1955) There is weighty evidence against the view that these viruses multiply by a mechanism similar to that of bacteriophages The early evidence that they divide by binary fission has received strong support through the recent observations of Swain (1955) and Gaylord (1954)

From 8 to 30 hours later, depending on the strain of virus, infection is manifest by the appearance of round bodies, approximately 800 mμ in diameter, called initial bodies Presumably by binary fission these bodies divide, and as they become more and more numerous they become smaller and smaller until the final elementary body stage is reached The

initial body may produce a cluster of granules enveloped in a membrane and a cementing matrix of a density depending on the strain of virus With dense matrix the structures appear homogeneous in stained preparations and are called plaques or morulae. With a light matrix the structures appear granular and are called vesicles. Both types develop into large vesicles that may contain both plaques and granules Tissue cultures reveal no obvious changes until the vesicles are fully developed, when the host cell is suddenly lysed The cytoplasmic plaques or inclusion bodies are true virus colonies made up of elementary bodies The exact nature of the matrix is uncertain Although findings in tissue cultures strongly indicate that it may be a product of the cytoplasm, it may be a secretion of the elementary bodies (Findlay, 1938).

About 30 to 54 hours after the beginning of the cycle, vesicles, morulae and possibly plaques break up, and lysis of the host cell releases several hundred to a few thousand elementary bodies Virus titers parallel the number of elementary bodies. Each elementary body can initiate new cycles in susceptible cells

Variations in this cycle are related to the strain of virus and to the susceptibility of living cells Virus colonies composed of particles invariably contain the virus antigen within the cytoplasm of infected cells (Buckley et al, 1955) During the early growth of mouse and feline pneumonitis virus in the mouse lung, extracellular growth in the alveolus has been seen Vesicles containing granules protrude into the alveolus, apparently attached to its wall (Loosli and Ritter, 1948; Weiss, 1949)

The entoderm cell of the yolk sac is susceptible to all agents of the group, and the yolk is a favorable medium for their survival (Weiss, 1955). Successful propagation of the virus in the chick embryo infected by the chorio-allantoic, the amniotic, the allantoic and the yolk-sac methods provides highly infective suspensions needed in serologic and

chick embryos, these viruses may vary considerably; feline and murine pneumonitis virus grow poorly. Psittacosis and ornithosis strains are readily grown in HeLa or monkey kidney cell tissue cultures, but the yield is low. They exhibit no special affinity for cells of the chick embryo and multiply in the most readily available cells. Infected allantoic fluid, yolk sac or mouse lung are useful for separating the elementary bodies from tissue components by procedures that include the use of proteolytic enzymes, surface active agents, absorption of cell components by specific antiserum or to celite and cycles of high and low-speed centrifugation (Zahler and Moulder, 1953) or simply by differential centrifugation (Gogolak and Ross, 1955). Purified preparations of meningopneumonitis virus were also obtained by dialysis against distilled water (Crocker, 1954). Fairly purified preparations have been obtained and are useful in a diversity of studies, but these procedures bring about considerable inactivation By means of ingenious counting methods it has been learned that 200 to 1,000 elementary bodies of meningopneumonitis (Crocker, 1954) or 20 to 100 feline pneumonitis particles (Moulder and Weiss, 1951) are required to infect chick embryos by the yolk-sac route A linear relationship between the feline pneumonitis concentration and the number of cells infected in tissue culture indicates that one single particle suffices to initiate infection (Weiss, 1955)

The electron microscope shows the size of elementary bodies to range from 350 mμ, meningopneumonitis and bovine enteritis viruses being the smallest, to 500 mμ, feline pneumonitis virus being the largest, various avian viruses and murine pneumonitis virus occupy intermediate positions (Kurotchkin et al., 1947). Filtration through graded collodion membranes and the sedimentation constant give less accurate measurements because the elementary bodies are too large for accurate ultracentrifugal studies The air-dried specimens present a uniform morphologic feature: there are a central zone of high electron scattering power with a wrinkled convoluted surface and a less dense peripheral zone. This outer component in the hydrated particle seems to be a membrane with osmotic properties (Heinmetz and Golub, 1948).

These viruses have an affinity for basic dyes, particularly basic fuchsin (Macchiavello method) and methylene blue (Castaneda method). They do not retain gentian violet

after decolorization with 95 per cent ethanol as well as the rickettsiae do Elementary bodies and larger forms are Feulgen positive

According to phosphorus determinations, the feline pneumonitis virus is of the same chemical complexity as rickettsiae and bacteria; both pentose and desoxypentose nucleic acids in the approximate ratio of 2 5 1 have been identified (Zahler and Moulder, 1953, Moulder, 1954).

The susceptibility of viruses of the psittacosis-lymphogranuloma group to common physical and chemical inactivation is relatively high. They are among the less stable viruses under ordinary laboratory conditions The agent of turkey ornithosis in 20 per cent mammalian tissue suspension has been destroyed in less than 5 minutes at 56° C. and in less than 48 hours at 37° C When a portion of the same suspension was stored at −20° C or at dry-ice-chest temperature for 400 days the virus was gradually inactivated until 99 95 per cent had been destroyed Diseased turkeys frozen in processing plants retained the ornithosis agent in a viable state after a little over a year of storage at −20° C or below When preserved in 50 per cent glycerol in buffered saline (pH 7 6) and held 0° ± 4° C heavy suspensions of infective tissue retained their activity for 10 to 20 days These viruses in sputum and human lung tissue rapidly lose potency in glycerol Formalin (0 1%) or phenol (0 5%) inactivate them in 24 to 36 hours, while ether or ethanol at room temperature is destructive within 30 minutes The pH range of stability is narrow, and the rate of inactivation by ultraviolet irradiation is comparable with that of *Escherichia coli* (Moulder and Weiss, 1951)

Studies dealing with the biochemical aspect of virus growth have furnished only a partial answer to the question: How do the host and the virus parasite participate in virus synthesis? The chemical composition of these viruses, their content of both kinds of nucleic acid, as well as lipid and protein-bound phosphorus, suggest a structural complexity compatible with independent enzyme activity This conclusion is supported by their susceptibility to chemotherapeutic agents known to inhibit bacterial enzyme systems (Moulder, 1954) In this connection the studies on growth factors (Hare and Morgan, 1954, Johnson and Morgan, 1956, Morgan, 1954, 1956) promise to reveal pathways of protein metabolism Virus multiplication has been brought to a halt by disturbing enzyme-substrate complexes and mechanism of catalysis, particularly with respect to metabolic cycles in protein synthesis beginning with certain amino acids, such as phenylalanine and tryptophan The present evidence suggests that the psittacosis-lymphogranuloma venereum viruses are active metabolic units

Early studies on the complex antigenic structure of these viruses showed that at least 2 antigens—one, a heat-labile antigen destroyed by temperature above 60° C, the other, able to withstand boiling or even autoclaving at 135° C—are associated with the elementary bodies of psittacosis (Bedson, 1936) Antigenic components associated with the virus particle are released into solution These are reactive in the hemagglutination, the complement-fixation, the dermal sensitivity and probably the toxin-neutralization tests (Weiss, 1955) The heat-stable component, constituting the bulk of antigen in the elementary body, acts in the complement-fixation and the hemagglutination tests It is the group-specific antigen shared by all recognized members of the group The heat-labile component is the strain-specific antigen shared only by some members, and the serologic activity of this antigen is always much the weaker of the two (Monsur and Barwell, 1951) It may be obtained by treating crude antigens with potassium periodate, which destroys the group component, leaving the rather fragile specific antigen. The marked heat stability of the group antigen and its destruction by periodate indicates that a carbohydrate fraction is a corporate member Now that better methods of purifying virus preparations have been developed, antigens have been identified that are responsible for group and specific reactions in complement fixation, virus toxin neutralization and dermal sensitivity Ether-soluble and ether-insoluble group complement-fixation antigens have been secured from ornithosis-infected yolk sacs (Volkert and Moller Christensen, 1955) Extraction of elementary body suspensions with lauryl sulfate has yielded a water-soluble group complement fixation and dermal antigen identified as a protein-carbohydrate-lipid

complex (Benedict and O'Brien, 1956). By centrifugation the complement-fixing antigen was sedimented, leaving in the supernatant fluid the allergenic antigen which elicits specific dermal reactions in infected turkeys (Benedict and McFarland, 1956). Further progress has been made in isolating alkali-soluble and ether-soluble complement-fixing antigens by chemical fractionation of purified psittacosis or feline pneumonitis elementary body suspensions disrupted by sonic vibration (Ross and Gogolak, 1957) The alkali-soluble fraction could be deprived of its group activity with either potassium periodate or cobra venum (lecithinase A), and thus psittacosis and feline pneumonitis species-specific antigens could be obtained Similar treatment of ether-soluble antigens yielded only group serologic activity Chemical analysis of the alkali-soluble fraction suggests that both the group and the specific serologic activity reside in a lecithin nucleoprotein complex Whether lecithin acts as a hapten in the serologic reactions or potentiates the nucleoprotein component is unknown. Allantoic fluid from duck embryos infected with psittacosis, murine or feline pneumonitis and meningopneumonitis viruses agglutinates mouse erythrocytes The serologic reaction is group- rather than strain-specific. The hemagglutinin consists of 2 chemical fractions: a phospholipid and a nucleoprotein. The former contains lecithin, which is not serologically specific but can agglutinate mouse red cells Specific hemagglutination inhibition takes place in the serum of roosters immunized with purified elementary bodies, indicating that hemagglutinins are associated with the virus particle (Hilleman et al, 1951; Gogolak, 1954, Gogolak and Ross, 1955).

Toxins produced in high concentration in the yolk sac of embryonated hen's egg heavily infected with these viruses is variably lethal to mice on intravenous inoculation (Cox, 1953) The toxicity is unstable; the potency declines at 4° C and is lost at 22° to 37° C. and is destroyed by 0 1 per cent formalin, although the antigenicity is retained The toxin is closely associated with the elementary bodies and is sedimented with the virus when centrifugated at 18,000 rpm for 60 minutes or when put through Seitz filters Certain toxins in the dilution of 1:1,000 (e g, that of the highly virulent turkey strains) kill 50 per cent of the mice within the first 16 hours after intravenous injection; later deaths presumably due to infection begin 24 hours after the inoculation. Using the suppressing effect of antibiotics, the death rate in the first period is often reduced as much as 50 per cent, indicating that some strains multiply rapidly enough to enter into the first phase of the diphasic death curves (Manire and Meyer, 1950). If homologous toxin-virus mixtures and antiserum are administered together, deaths due to the toxin do not occur Potent antiserum produced by hyperimmunization of roosters neutralizes both virus and toxin As a rule, from 80 to 90 per cent of the mice survive at least 48 hours During the following 8 days a variable percentage, never exceeding 50 per cent, succumb to infection Not all strains produce 2-phase death curves Some strains are not lethal by the intravenous route; others with very lethal toxins are rapidly lethal; the death curve is then characteristically monophasic The most potent toxin-producing strains are generally, but not always, associated with the viruses recovered from severe to fatal human illnesses, e g, Louisiana, Illinois and turkey viruses. The toxin-producing ability of most avian strains varies, of the mammalian strains only the enzootic abortion of ewes virus produces a potent toxin The toxin neutralization technic is of value in distinguishing the avian from the mammalian strains (Meyer, 1954)

In numerous publications since 1952 Giroud and his associates have called attention to a diversity of syndromes in man and animals which, according to their interpretation of virus isolations and serologic tests, are caused by intracellular agents related to the psittacosis group, but they have placed the responsible organisms in the newly created genus *Neorickettsiae* Using a micro-agglutination and a very sensitive complement-fixation test with antigen prepared from an Argentinian parrot virus (T13) they discovered that serum of man and cattle, sheep, dogs and cats in Africa, Central America, the Far East and Europe reacted with high specificity and in high dilutions not infrequently with their antigen and quite often simultaneously with a rickettsial agent isolated from a case of exanthema (X14) These extensive reports in

general indicate that certain rickettsiae contain antigens related to the psittacosis group antigen, and that infections with these parasites must be considered in the diagnosis of psittacosis when there is no known association with the usually recognized reservoirs

Another interesting antigenic relationship has been discovered—between an ornithosis virus and certain coccoid bacteria related to the anitratum bacteria (Volkert and Matthiesen, 1956). Human ornithosis positive sera tested with the bacterial antigen showed a positive reaction with the same titers as those obtained with the ornithosis antigen The bacterial culture absorbed at least some of the ornithosis antibody Bacteria of the anitratum group are very common in the respiratory tract of human beings If under certain circumstances these bacteria can produce antibodies reacting with ornithosis antigen, an explanation of some of the false positive reactions may be at hand

The persistence of psittacosis parasites in their hosts in a state of well-adjusted parasitism explains the relative immunity to this infection Probably most patients recovering from psittacosis are resistant to reinfection Second attacks have been observed, and some have been reported (Meyer, 1939-40) One patient after recovery continued to shed virus in the sputum 8 years after severe clinical psittacosis (Meyer and Eddie, 1951) Recovery from an inapparent infection with the turkey virus probably gives no protection against a psittacosis virus These observations are compatible with the recognition that members of the group possess species-specific antigens (Hilleman, 1945, Ross and Gogolak, 1957) The immune reaction of the host consists of the production of antibody barriers against spread of the viruses Using a delicate technic, neutralizing antibodies were found in the serum of some human beings who have a history of psittacosis and of primates recovered from psittacosis (Rivers and Schwentker, 1934) The neutralization of viral activity by antiserum is valuable in identifying many members of the group (Hilleman, 1945, Meyer, 1954) After recovery from psittacosis or during active immunization with active or inactivated virus, specific antibodies are demonstrable in the serum of mammals, including man, and birds. Particularly useful are the complement-fixation and the precipitation tests and the agglutination test (Lazarus and Meyer, 1939) The hemagglutination-inhibition and the conglutinating complement-absorption test (Hilleman et al, 1951) and the indirect complement-fixation test have been used to study the infection in birds (Karrer et al, 1950) The role of opsonins in the serum of recovered animals and the destructive action exerted by monocytes derived from immune mice have been studied in preliminary experiments (Meyer, 1941a; Yanamura and Meyer, 1942) Persistence of serum antibodies at high titer for months after recovery is usually associated with latency Simultaneously, a state of hypersensitiveness is demonstrable by intradermal injection of suitable specific antigens either prepared by extraction of suspensions of psittacosis virus with hydrochloric acid (Bedson et al, 1949) or by special purification (Benedict and McFarland, 1956)

Hyperimmunization with formalized psittacosis vaccine did not completely prevent multiplication of the virus in mice (Bedson 1938) Immunity was effective when immunizing and challenging doses were given by the intraperitoneal route (Yanamura and Meyer 1942), but mice hyperimmunized by the intraperitoneal route with killed vaccines resisted at best 10 intracerebral or intranasal LD_{50} (Wagner et al, 1946) Considerable immunity may be conferred by formalized noninfective vaccines in parakeets and ricebirds (Meyer et al, 1942), and in ewes, formalin-inactivated enzootic abortion virus has eliminated abortion if the vaccine, prepared from infected ovine fetal membrane tissues, was incorporated in an adjuvant (McEwen and Foggie, 1956) A more effective immunity has been obtained with living virus vaccines In guinea pigs inoculated intradermally with virulent psittacosis or murine pneumonitis strains, resistance to intratracheal challenge was developed with 40 respiration LD_{50} doses (Wagner and Victor, 1953) These results are similar to those of an earlier experiment of Rivers and Schwentker (1934) in which monkeys were immunized against intratracheal inoculation by intramuscular injection of small doses of virulent psittacosis virus. Cross-immunity studies indicate that the San Francisco, Illinois and Louisiana strains are rela-

tively homotypic, strains of psittacine origin are less specific, and the ornithosis viruses have broad antigenic structures (Wagner et al, 1949) The method offers too many obstacles to bring strain relationship into categorical positions

Diagnosis

The clinical picture, the results of physical examination and the roentgenogram give useful but not pathognomic information. The symptoms and the history of contact with birds, wild or domestic, living or dead, justify bias in favor of the diagnosis Unfortunately, these must suffice to guide the physician in the care of his patient, because the results of the only certain tests are often not available until the peak of the acute phase has passed Familiarity with the illness in all of its forms—from the mild, atypical, ambulatory, influenzalike disease to the toxic fulminating pneumonitis—should lead the physician to ask the questions necessary to link the patient to the source of his infection In the individual case the success of antimicrobial therapy might seem to obviate the need for diagnosis of this infection altogether But epidemicity is one of its disturbing characteristics, spread from person to person is not unheard of, and the mortality rate is still not negligible The source of one infection may be the source of one or many more

Proof that the illness, not necessarily respiratory, is psittacosis rests on fulfilling the following criteria (1) The viral agent must be isolated during the acute or chronic phase or at autopsy. (2) Complement-fixing, agglutinating or neutralizing antibodies must be found during convalescence or, more certain, the titer of these antibodies must rise during recovery (3) The pathologic, anatomic and experimental examinations of diseased or dead birds in the patient's environment must reveal this agent The probability that these criteria will be met is declining

For primary isolation, blood, sputum, throat washings, vomitus or emulsions of organs are injected intraperitoneally or intranasally into mice, or when free from bacterial contamination, into embryonated eggs (cf Meyer and Eddie, 1956a). These specimens must be taken before treatment Parakeet, parrot and some turkey viruses produce fatal infections in mice by the intraperitoneal route Those from pigeons, ducks and chickens must be enriched through passage first by the intraperitoneal route and then by the intranasal or the intracerebral route for microscopic examination

Between 1931 and 1944 virus was isolated from the specimens of 55 (24%) of 227 clinically and epidemiologically diagnosed cases of psittacosis. Between 1945 and 1953 the proportion of isolations dropped to 23 (4 7%) in 481 specimens (Meyer, 1955) Probably this can be accounted for by treatment with antimicrobial drugs before the collection of the necessary specimens This is regrettable, because the study of isolated strains provides the epidemiologist and the public health worker with knowledge required.

The complement-fixation test has been applied with increasing precision to establish that a given acute illness in man or animals is caused by a member of this group The antigens commonly prepared from infected yolk sac, allantoic fluid, mouse spleen, lung or peritoneal exudate (Brand and Lippelt, 1954) are group antigens enhanced in antigenicity by boiling, treatment with phenol, ether or urea An important feature of the serologic relationship among members of the group is their extensive sharing of antigens, responsible for cross reactions in this test Lygranum, a commercial lymphogranuloma-venereum antigen, has been used most often for routine diagnostic work, but it is unwise to depend on it for consistent revelation of antibodies against psittacosis or ornithosis viruses (Whitney and Gnesh, 1954, Meyer and Eddie, 1956a). Homologous antigens provide better results (Bucca, 1957), and the time has arrived to insist that the reference laboratories distribute strain-specific antigens prepared according to the method of Ross and Gogolak (1957).

Complement-fixing antibodies against these viruses appear in exceptional instances before the 12th day after onset Average maximum titers of 1 64 to 1:256 and in rare instances above 1.512 may be reached by the 20th to the 30th days The reaction is subject to wide individual variations The titer may decline within the first 4 months, or it may persist or decline over a period of several years Treatment may partially block or delay antibody

formation. Anamnestic titers rise in other infections, for example in brucellosis or Q fever. If suspicions persist despite the absence of a demonstrable rise in the convalescent specimen, a 3rd or even a 4th should be examined. In cases in which treatment has been vigorous and the test made repeatedly, antibodies have not yet appeared even after 3 months (Meyer and Eddie, 1956a). Anamnestic reactions usually have disappeared by the 30th to the 40th days, while in true psittacosis the titer will usually rise as recovery proceeds. Antibody due to inapparent or latent infection with lymphogranuloma-venereum virus may be a serious cause of confusion. For example, if Caucasian workers in a poultry-processing plant have no antibody to psittacosis, the titers in the Negro workers is more likely to be due to lymphogranuloma venereum, the incidence of overt and latent infection is decidedly higher in the latter than the former (Mandel and Jordan, 1952). Persons who are exposed to psittacosis or ornithosis virus—aviary owners, pet-shop employees, workers in poultry plants—may show clinically insignificant complement-fixing antibodies in their serum in titers up to 1:32.

Despite the often-repeated admonition that a meticulous environmental history is essential, in over 25 per cent of the officially listed cases the source of infection has not been established. Isolation of virus is the most conclusive method in individual birds, but this time-consuming method need not be used to detect flock infections. The complement-fixation test is relatively simple and rapid (Kissling et al, 1956). Chicken, duck and turkey sera are seldom positive in this test because they block the usual reaction. The indirect or inhibition complement-fixation test, on the other hand, has yielded valuable information about the extent of ornithosis in poultry flocks (Karrer et al, 1950, Meyer, 1952). For parakeets it is better to use both tests (Kissling et al, 1956). Using detergent-extracted antigens, the direct test has been used for diagnosis of ornithosis in turkeys (Benedict and McFarland, 1956).

Work is being done on the development of other tests that may be of clinical use—the rapid agglutination test, similar to the Brucella plate test (Mason, 1957), a capillary tube technic similar to that for *Rickettsia burneti* (Mason, 1957) and a skin test (Benedict et al, 1955, 1956). The hemagglutinin-inhibition and the conglutinating complement-absorption tests (Hilleman et al, 1951) are mainly research tools. The technics used to identify and classify isolates are: (1) pathogenicity and toxicity tests in different species of animals, (2) cross-immunity tests, (3) complement-fixation tests with strain-specific antigens and serum and (4) toxin and virus infectivity neutralization tests for demonstration of specific serotypes (Meyer, 1955).

Treatment

Drug therapy has scored noteworthy successes. The early studies are largely of interest in respect to the dynamics of virus infection, particularly in delaying or stopping virus multiplication without complete eradication, thereby allowing development of a carrier state. Since 1950 interest has been centered on tetracycline compounds, because these have been quite effective in treatment, given proper conditions to terminate the infection. In chick embryos chlortetracycline is 5 times [redacted] effective as chloramphenicol on a molecular basis, and 3 times as effective on a weight basis. Tetracycline and oxytetracycline are superior to chlortetracycline in suppressing feline pneumonitis (Katz, 1956), Oxamycin is inferior to chlortetracycline but does lengthen the survival time of embryos infected with feline pneumonitis virus (Cuckler et al, 1955). Erythromycin, Xerosin, nitroacridin 3582 are somewhat active. Chlortetracycline is the preferred drug for human psittacosis caused by psittacine, ornithine and mammalian strains (Fitz et al, 1955). Prompt symptomatic improvement is commonly assured, provided that treatment is begun early with large enough doses and is continued long enough. Inadequate therapy may be followed by relapse. Broad-spectrum antimicrobial drugs did not control pigeon ornithosis virus infection in infants (Berman et al, 1955). It may be that in these cases the drugs, being merely virustatic, received little or no support from immunogenesis, which failed in the malnourished infants suffering from gastro-enteritis and dehydration.

Early studies on treatment of avian psittacosis and pigeon ornithosis were discouraging, but in later studies daily parenteral or oral

tively homotypic, strains of psittacine origin are less specific, and the ornithosis viruses have broad antigenic structures (Wagner et al., 1949) The method offers too many obstacles to bring strain relationship into categorical positions.

Diagnosis

The clinical picture, the results of physical examination and the roentgenogram give useful but not pathognomic information The symptoms and the history of contact with birds, wild or domestic, living or dead, justify bias in favor of the diagnosis. Unfortunately, these must suffice to guide the physician in the care of his patient, because the results of the only certain tests are often not available until the peak of the acute phase has passed Familiarity with the illness in all of its forms—from the mild, atypical, ambulatory, influenzalike disease to the toxic fulminating pneumonitis—should lead the physician to ask the questions necessary to link the patient to the source of his infection. In the individual case the success of antimicrobial therapy might seem to obviate the need for diagnosis of this infection altogether But epidemicity is one of its disturbing characteristics, spread from person to person is not unheard of, and the mortality rate is still not negligible The source of one infection may be the source of one or many more

Proof that the illness, not necessarily respiratory, is psittacosis rests on fulfilling the following criteria· (1) The viral agent must be isolated during the acute or chronic phase or at autopsy (2) Complement-fixing, agglutinating or neutralizing antibodies must be found during convalescence or, more certain, the titer of these antibodies must rise during recovery (3) The pathologic, anatomic and experimental examinations of diseased or dead birds in the patient's environment must reveal this agent. The probability that these criteria will be met is declining

For primary isolation, blood, sputum, throat washings, vomitus or emulsions of organs are injected intraperitoneally or intranasally into mice, or when free from bacterial contamination, into embryonated eggs (cf Meyer and Eddie, 1956a). These specimens must be taken before treatment. Parakeet, parrot and some turkey viruses produce fatal infections in mice by the intraperitoneal route Those from pigeons, ducks and chickens must be enriched through passage first by the intraperitoneal route and then by the intranasal or the intracerebral route for microscopic examination.

Between 1931 and 1944 virus was isolated from the specimens of 55 (24%) of 227 clinically and epidemiologically diagnosed cases of psittacosis. Between 1945 and 1953 the proportion of isolations dropped to 23 (4 7%) in 481 specimens (Meyer, 1955). Probably this can be accounted for by treatment with antimicrobial drugs before the collection of the necessary specimens This is regrettable, because the study of isolated strains provides the epidemiologist and the public health worker with knowledge required

The complement-fixation test has been applied with increasing precision to establish that a given acute illness in man or animals is caused by a member of this group The antigens commonly prepared from infected yolk sac, allantoic fluid, mouse spleen, lung or peritoneal exudate (Brand and Lippelt, 1954) are group antigens enhanced in antigenicity by boiling, treatment with phenol, ether or urea An important feature of the serologic relationship among members of the group is their extensive sharing of antigens, responsible for cross reactions in this test. Lygranum, a commercial lymphogranuloma-venereum antigen, has been used most often for routine diagnostic work, but it is unwise to depend on it for consistent revelation of antibodies against psittacosis or ornithosis viruses (Whitney and Gnesh, 1954; Meyer and Eddie, 1956a). Homologous antigens provide better results (Bucca, 1957), and the time has arrived to insist that the reference laboratories distribute strain-specific antigens prepared according to the method of Ross and Gogolak (1957).

Complement-fixing antibodies against these viruses appear in exceptional instances before the 12th day after onset. Average maximum titers of 1 64 to 1:256 and in rare instances above 1:512 may be reached by the 20th to the 30th days. The reaction is subject to wide individual variations The titer may decline within the first 4 months, or it may persist or decline over a period of several years. Treatment may partially block or delay antibody

ington, bringing the total for 1956 to 134 cases, and 27 from British Columbia in 1957. It has been estimated unofficially that 486 cases (12 deaths) have been contracted through exposure to turkeys in these places. Serologic surveys have indicated that flocks carry latent infections in California, Michigan, Minnesota, Massachusetts, Ohio and Arizona. Samples of normal and moderately enlarged spleens from 2 flocks in California and Michigan have yielded isolates of low or moderately high virulence. These have caused no known human infections. In contrast, the highly virulent strains isolated from turkey flocks during epizootics caused human attack rates as high as 48.2 per cent in the processors. The sources of infection and mode of spread, in fact the whole ecology of turkey ornithosis, are not known.

Obviously, both psittacine and extrapsittacine birds serve as reservoirs and transmit the virus to man. In 1954 nearly 60 per cent of the 563 cases officially reported were attributed to sources other than psittacine birds. In fact, of the 1,610 cases on record for 1952 to 1956 (first 9 months), the source of infection was learned in 808. 448 (55%) were of psittacine and 360 (45%) of extrapsittacine origin, mostly turkeys. Human infections directly traceable to mammals are either unrecognized or occur infrequently. Only 2 laboratory infections one proved through isolation of enzootic abortion virus from the sputum (Barwell, 1955) and the other by isolation of bovine encephalomyelitis virus from the blood (Meyer and Eddie, 1956b), furnish evidence that the mammalian viruses can infect man. There is additional evidence in the antibody response of veterinary personnel in stockyards (Enright and Sadler, 1954) and sheepherders (Gerloff and Lackman, 1954) in the United States. An infection among natives in the Belgian Congo has been attributed to the related *Neorickettsia* by Giroud and Jadin (1954), who have suggested that these outbreaks may have originated from cattle, sheep or goats.

The epidemiologist must carefully investigate every known and even unknown avian and mammalian source, rather than rely solely on the possibility of human spreaders of the virus.

With removal of virtually all restrictions on the movement of psittacine birds in 1951, mainly in the United States, the exploitation of a nation-wide market for domestically reared and illegally imported parakeets has increased the annually reported cases from 135 in 1952 to 563 in 1954 and 508 in 1956. The reported case rate per million population for 1952 was 2.3, for 1954, 4.3, while the number of pet birds in the United States rose from about 3 million in 1940 to around 15 million in 1953. In other words, the psittacine population increased many more times than the reported case rate.

In the past, single cases undoubtedly escaped detection; old reports deal principally with house epidemics which established the pattern now so well known of the psittacosis epidemic. The great epidemics of the past occurred during the winter probably because of prolonged exposure to infected avian pets in closed rooms of a winter household. Severe infection on the Faeroe Islands and among pigeon fanciers the world over is not uncommon in midsummer and early fall. It now seems probable that it can be contracted throughout the year. Its higher incidence among people of middle age or older has been stressed, but the evidence is open to question. These people may be more likely to acquire birds as pets and to spend more time in closed households. Infants and children under 5 years of age have contracted fatal infection (Berman et al., 1955), and severe illness has been observed in the age group 10 to 20 years (Strobel, 1954). The disease has a greater incidence among women than men. The fairly constant ratio of 2:1 may be ascribed to their activities as parakeet breeders or bird-lovers. Men and women are probably equally susceptible. In processing plants under identical conditions of exposure the attack rates are nearly identical. The higher attack rate in non-Caucasians in processing plants reflects more the nature of the work—killing, defeathering and eviscerating—than susceptibility. Psittacosis is a fairly common occupational infection among persons engaged in raising or trading in parakeets or pigeons and in transporting parakeets (Seibert et al., 1956).

The ways the infection may be contracted, in order of importance, are by inhalation, possibly by the gastro-intestinal tract and through bite wounds. The ease with which inhalation of virus induces pneumonic lesions in susceptible mammals points directly to the respiratory tract as the principal entry for the virus. Handling of sick or dead birds or contact with feathers soiled with infective discharges or excreta or with droppings from latently infected flocks—all capable of creating virus-carrying aerosols—are fully proved modes of infection. The clinical nature of the

therapy with 30 mg per Kg of tetracycline compounds has improved the health of individual parakeets, reduced mortality, prevented epizootics and reduced the hazard of infection in aviary personnel. It does not always eliminate the carrier state in every bird, but if treatment of aviaries is repeated at regular intervals, ultimately the infection may be eradicated (Meyer et al., 1958). Attempts to eradicate ornithosis from pigeon flocks remain disappointing Prolonged treatment with large doses of tetracycline compounds is required to eliminate the carrier stage in parrots During epizootics of ornithosis in turkeys treated with pharmacologically inadequate doses of tetracycline compounds (400 Gm. per ton of feed) for 15 to 30 days the mortality was arrested and the birds visibly improved. But virus persisting in the anatomic lesions and the viscera caused infection in the personnel of processing plants handling the treated birds

The action of these compounds in vitro and in vivo is suppression of multiplication, in particular division of initial bodies (Weiss, 1955) One assumption is that these compounds interfere with some metabolic process essential for reproduction (Moulder, 1954) In addition to their susceptibility to chemotherapeutic agents, one of the characteristics of these viruses is their ability to develop drug-resistant mutants in egg and mouse passage The development of drug resistance in viruses that tend to chronicity may seriously impair the programs designed to eradicate psittacosis from poultry or parakeet stocks by treatment (Gordon et al, 1957)

Epidemiology

The avian sources of infection in man have changed since the outbreaks of 1929 and 1930 Of great significance was the discovery that in the United States and Germany visibly healthy relatives of the parrots, the parakeets, were prolific disseminators of psittacosis virus. For a time after 1932 nearly all reported cases in man were derived from psittacine birds Enzootic and occasionally epizootic psittacosis was proved in aviaries and pet shops in the United States and Europe [illegible] et al., 1956) and from these res- [illegible]

supports the belief that [illegible]

[illegible] parrots, parakeets and [illegible]

ological gardens have been high at times either because the birds had not been immunized by nest infection or because relapses were brought about by low temperature, crowding in dirty cages and improper feeding Shortly after fulmars or petrels were the sources of human illness and death on the Faeroe Islands, in the United States birds other than psittacine were found to be spreading the infection. Then it was learned that pigeons are potential sources, and according to reports from nearly every country in the world where studies have been instituted ornithosis is widespread among wild and domestic pigeons (Mohr, 1954). Squabs with extensive lesions may infect the person who dresses them An increasing literature from Holland, England, France, Italy, Germany, Israel, Mexico and Australia attests to the widespread symptomatic and more often inapparent ornithosis infection in pigeons (Weyer and Lippelt, 1956; Kemmerer et al., 1956) Serologic evidence of ornithosis in ducks in Michigan was subsequently supported by isolation of the virus both from healthy and from diseased ducklings from that state (Meyer and Eddie, 1952) and from ducks on farms in California and Long Island Histories of mild cases of atypical pneumonia among duck handlers were identified as psittacosis in Long Island and Virginia (Andrews, 1957). Serious economic losses among ducklings on farms and more than 100 human infections among women plucking ducks have been reported from Czechoslovakia since 1949 (Konrád and Strauss, 1955).

Chickens (Karrer et al, 1950) and pheasants (Ward and Birge, 1952, Ward et al, 1954) have been incriminated and proved to be infected, though few cases of transmission to man have been reported.

Reports on outbreaks among turkey-processors in Texas (Irons et al, 1955; Irons et al, 1956) call attention to a suspected episode as early as 1938. Since 1948, 7 authentic outbreaks among turkey-dressers have been discovered. During 1954 an outbreak was reported from New Jersey, and another involving husbandrymen, processors and even renderers (86 cases in all) occurred in Oregon in 1956 Thirty-four cases (1 death) followed the dressing and the cleaning of turkeys in 2 plants in Texas; 10 cases have been reported from Wisconsin, 4 from Wash-

History

John Hunter in 1786 described inguinal buboes in the male, and in 1833 Wallace described them and their accompanying constitutional symptoms in greater detail Desruelles gave an excellent account of 2 cases of vulvar hypertrophy following the involvement of the inguinal lymph nodes Hugier is credited with giving the name "esthiomene" to the characteristic induration and discoloration that involves the affected parts Multiple abscesses in inguinal adenitis were originally described by Velpeau, and Nélaton and Tanton and Pigeon recognized them to be the nontuberculous manifestations of an unknown disease (Koteen, 1945). Suppurative inguinal adenitis was described as climatic bubo and attributed to plague, malaria and fatigue, until Rost in 1912 realized that it is a venereal infection Klotz first described the disease in the United States, calling it strumosen Bubonen, and was the first to note the penile lesions, Durand, Nicolas and Favre, 1913, brought these manifestations into one disease entity, subacute inguinal lymphogranulomatosis, transmitted sexually, and they conclusively differentiated it from syphilis and tuberculosis But because of its close resemblance to Hodgkin's disease they sanctioned the designation lymphogranuloma inguinale Phylactos, a pupil of Favre, called it the fourth venereal disease, but emphasized that its characteristics were identical with those of climatic bubo

For a time there appeared to be no correlation between lymphogranuloma venereum and the seemingly independent genital diseases observed by gynecologists and surgeons for nearly 100 years—troublesome ulceration and elephantiasis of the female pudenda—and inflammatory stricture of the rectum Though lymphogranuloma venereum was often associated with venereal disease, its origin was clarified only with the development of the Frei test, and within a few years a bacteria-free meningitis was produced in rhesus monkeys by intracerebral inoculation of pus from a bubo (Hellerstrom and Wassen, 1930)

With introduction of the mouse as a suitable laboratory animal for study of this disease and the finding of virucidal antibodies by Levaditi et al, 1932, began the investigation of lymphogranuloma venereum as a virus infection Gamma, 1924, described large bodies in the cytoplasm of cells from infected lymph nodes, but their nature remained uncertain The small granules reported by Gay Prieto, 1927-28, and the granulocorpuscles of Miyagawa et al (1935) were recognized by Findlay (1938) and by Rake and Jones (1942) as elementary bodies derived from larger initial bodies in an interesting developmental cycle Lymphogranuloma venereum virus was among the first in the group to provide evidence of a thermostable endotoxin and to be found sensitive to sulfonamides

Clinical Picture

Usually within a few days after venereal exposure the initial lesion develops on the glans and the prepuce of the penis, the posterior aspect of the labia, the vaginal walls, the cervix, within the urethra or in the region of the anus This vesicle, also known as the herpetiform lesion of Cole, 1933, bursts, leaving a shallow, grayish ulcer of lymphogranulomatous chancre The clean-cut edges surrounded by a narrow band of reddened skin are not indurated In a rare case the initial lesion is on the tongue or the conjunctiva The vesicle may be painless and therefore overlooked or it may be ignored The infection may terminate at this stage, or it may proceed to the second stage Laboratory infections attest that the disease may have minimal symptoms mild fever fleeting muscle pains and malaise

The second stage is characterized by involvement of the regional lymph nodes, usually in the groin, rarely in the neck, the axilla or the oculoglandular region Pain in the groin and enlargement of the nodes may be the only symptoms When the primary lesion is intra-urethral or anorectal, the infection spreads to the pelvic nodes The lymph drainage of the vagina favors involvement of the intrapelvic the perianal and the deep pelvic nodes In the male the buboes form in the inguinal nodes, at first only discrete, slightly tender and movable Later they adhere to the underlying tissues and form a large, single, tender inflammatory mass In most patients in the temperate zone the adenitis is unilateral, in the tropics it is usually bilateral It may resolve spontaneously, but in about half the cases the nodes suppurate The infection may be confined to the lymph nodes, or it may become more generalized

The adenitis may be accompanied by chills,

illness is related to the dose and the virulence of the virus (Gordon, 1957) and to the portal of entry Little is known about the possibility of infection of man by the gastro-intestinal route. Bovine enteritis virus is excreted in the feces of cattle, and when it is fed to calves induces illness, but the relation of this and the psittacosis and the ornithosis viruses, also excreted, to human disease is unexplored. It seems possible that psittacosis virus might be swallowed after hand-to-mouth transmission from the environment of an infected bird. As far as is known, human beings have not contracted ornithosis by ingestion of infected poultry. When concentrated highly infectious suspensions of the turkey ornithosis agent

man is greatly diminished because ordinarily poultry ■ cooked thoroughly enough to destroy most, if not all, the virus particles.

Infections in laboratory personnel and animal caretakers fully attest to the extreme contagiousness of the disease, which demands utmost caution in the handling of the diverse specimens suspected of carrying the virus *The infection may also spread from person to* person (Berman et al, 1955, Babudieri and Cerri, 1956). At least 23 reports, involving 30 nurses, are known The 1943 epidemic of severe pneumonitis in the bayou region of Louisiana, with a toll of 8 deaths in 19 recognized infections among nursing attendants, emphasizes the importance of direct contact in human-to-human transmission. In one instance a patient known to be a psittacosis carrier for 8 years did not transmit the infection (Meyer and Eddie, 1951)

The case fatality rate for the outbreak years 1929 and 1930 was nearly 20 per cent, *in some outbreaks 40 to 100 per cent, but* with the recognition of more mild infections the rate was about 10 per cent Then with the introduction of antimicrobial drugs it has fallen to 5 per cent in the United States and to 3.5 per cent (86 cases) in Germany (Haussman et al., 1956) It could be kept even lower if early diagnosis and proper treatment were instituted. Most of the patients who died were 40 to 60 years old

Control Measures

Psittacosis is a minor health problem.

parakeets during shipment from mass collecting centers to pet shops and finally the consumers to warrant the organization of preventive programs. With the aid of chemotherapy, immature parakeets could be mass produced, freed from infection, distributed and sold through pet shops Suppression of this infection chain would greatly reduce the number of human infections acquired in homes Educational campaigns must continuously warn the public and physicians to understand the danger from contact with apparently healthy birds Prohibition of taking young fulmars onto the Faeroe Islands has terminated the yearly outbreaks of severe pneumonia The incompletenes of ecologic information on ornithosis in turkey flocks makes it exceedingly difficult to plan and to carry out control measures Chemotherapy with tetracycline drugs has failed to sterilize the virus-laden visceral lesions and to prevent the occupational hazards among workers in processing plants and the marketing of diseased turkeys (Meyer, 1955). In view of the gratifying results in epizootic abortion of ewes through immunization with inactivated virus in adjuvants the prophylactic possibilities of vaccines should be re-explored by the poultry industry until methods have been developed to create and maintain flocks free from infection. Immunization of human volunteers against psittacosis has been carried out with dilutions of active virus subcutaneously. How effective such or improved procedures might be in control of the disease in man is not known

LYMPHOGRANULOMA VENEREUM

(Synonyms: Climatic bubo, tropical bubo, venereal bubo, fifth venereal disease, lympho-

Introduction

This disease is manifested by constitutional symptoms and by acute and chronic tissue changes in the inguinal and the recto-anal regions The virus is related to psittacosis virus in that its developmental cycle includes visible large elementary bodies in mononuclear cells

bits accept the infection more readily than older animals Fowl, pigeons, ricebirds and parakeets fail to react to intracerebral injections of highly infectious passage virus

Infection has been initiated by injecting mice intracerebrally with monkey-passage virus or with human material Of 26 strains transmitted to mice, only 2 were highly virulent; others lost their infectiousness on passage The 2 virulent strains produced symptoms of meningitis in 2 to 4 days. Many strains, when injected intracerebrally, induce, after an incubation time of 7 to 14 days, muscular in-co-ordination, paresis and weakness, with a mortality rate of 12 to 39 per cent In such mice the histologic findings are those of leptomeningitis, and impression preparations from the meninges furnish excellent material for study of the large and the small viral elements Intranasal administration of virus incites a pneumonic process that may be fatal between 4 and 6 days, it is characterized by desquamative alveolitis, nodular inflammation around the capillaries and the lymphatics and the formation of virus elementary bodies When the virus is injected intraperitoneally it localizes in the brain if starch is injected intracerebrally. It may be successfully passaged through the testes of mice

To produce models of the human disease, monkeys have been infected by the intraperitoneal, intrapreputial, intracutaneous, intrapulmonary and intra-ocular routes, and in the tissues of the intestine, the rectum and lymph nodes Typical inflammation develops locally, and the virus was readily demonstrable in the enlarged regional lymph nodes Neither the intravenous nor the intraneural route will establish infection in this animal.

Etiology

The infective agent is a large elementary body virus that passes through its development in the cytoplasm of reticuloendothelial cells Elementary bodies may be demonstrated in cells from human lesions, and they are transferable to experimental animals. They are agglutinated by specific antiserum and serve as specific antigens in the complement-fixation and intradermal tests Observations on the growth cycle of this virus have been correlated in a detailed study by Rake and Jones (1942), who investigated its multiplication in the yolk sac Its structure, developmental forms and staining characteristics place it in the psittacosis group All the basic characters of this group apply, with the exception of minor differences, in particular the species specificity of the antigens

The filterability is not constant By use of gradocol membranes according to Elford's method, the diameter of the infective viral body has been estimated at 120 to 180 mμ Electron micrographs of the elementary bodies propagated in the yolk sacs of developing chick embryos revealed a mean diameter of 438 ± 47 mμ (Kurotchkin et al, 1947) At 37° C the virus remains active from 2 to 4 days, while at 56° C it loses its power to infect within 10 minutes To keep it alive for a year or longer it is best held at −30° to −70° C Ultraviolet radiation renders it noninfective within 30 minutes In 50 per cent neutral glycerol the activity is retained for only a week or two Formalin (0 1%) or phenol (0 5%) inactivates it in 24 to 48 hours Ten per cent ether at room temperature inactivates it in yolk-sac suspensions within 30 minutes This virus can be cultivated in tissue cultures By propagation in the embryonated egg it yields highly infective (LD_{50}, 10^{-8}) suspensions useful for biologic and immunologic studies

Rake and Jones (1944) reported isolating a toxic substance readily demonstrable in heavily infected yolk sacs of moribund embryos It kills young mice rapidly after intravenous injection, if the activity is high and the dilutions are made in the allantoic and the amniotic fluids, it occasionally kills after intraperitoneal injection It is labile, readily inactivated at room temperature and by chemicals It produces hemorrhages in the lungs of mice

Yolk-sac suspensions or extracts contain the heat-stable antigen common to all viruses of this group It gives specific complement-fixation reactions in the presence of serum from lymphogranuloma venereum patients Aside from boiling, the reactivity of the yolk-sac suspension is greatly intensified by the addition of phenol, which suggests that the complement-fixing antigen is probably a lecithin nucleoprotein complex Destruction of the group activity with either potassium periodate or lecithinase should produce a

sweats, fever, prostration, loss of weight, anorexia, nausea, vomiting, pains in the thorax and the muscles, stiffness of the neck, headache, epistaxis and bronchitis. Scarlatiniform rashes and those resembling erythema multiforme have been reported If the infection becomes generalized all lymph nodes, the spleen and the liver may enlarge. The virus is frequently disseminated throughout the body; it has been recovered from the circulating blood, the spinal fluid and material obtained by puncture of the spleen while the buboes are present. Moderate secondary anemia and leukopenia are common. When the nodes suppurate there is often leukocytosis with relatively slight mononucleosis The erythrocyte sedimentation rate is usually increased Hyperglobulinemia with elevated total serum proteins and reversal of the albumin-globulin ratio is common. In severe cases this stage may progress to pneumonitis or to meningoencephalitis Conjunctivitis with oculoglandular syndrome has also been recognized.

The tertiary stage presents itself early or late in the infection in well-defined syndromes or in isolated or associated manifestations in different organs or systems. The more easily recognized are esthiomene, urethrogenitoperineal syndrome, elephantiasis of the penis and scrotum, rectal stenosis and plastic induration of the penis The esthiomene frequently mentioned in the literature is a nondestructive elephantiasis of the preputium, the clitoris or the labia minora. It sometimes extends to the labia majora and other soft parts of the vulva and the anus The effect of the infection on pregnancy is evidently minor The specific proctitis usually arises from spread of the infection from perirectal tissues through the rectal wall. Early in this proctitis the patients have little or no pain If it is not treated, the sequelae may be rectal stricture or vaginorectal or vaginovesical fistula Complete obstruction is uncommon, but the chronic process is frequently complicated by perirectal and perianal abscess and fistula Rectal stricture formerly erroneously attributed to injuries, syphilis or other causes is now being recognized as a sequel to lymphogranuloma venereum (Coutts, 1950).

The clinical characteristics are very well described by Favre and Hellerstrom (1954).

Pathologic Picture

There are no characteristic tissue changes in the lymphogranulomatous chancre; the area surrounding the ulcer is infiltrated mostly by plasma cells and histiocytes containing inclusion bodies The reaction in the lymph

same as that in inguinal and pelvic lymph nodes At times the lesions have some characteristics of those seen in tuberculosis and syphilis, but an experienced pathologist can make the distinction The inflammatory process consists of a great outpouring of mononuclear elements, especially plasma cells, a few neutrophils and eosinophils, and proliferation of the macrophages with giant-cell formation. Epithelioid transformation of the macrophages gives rise to peculiar tubercle-like nodules, which undergo necrosis There is, in addition, marked proliferation of fibrous tissue which, as the lesions heal, contracts, producing

tendency

gro may

the frequency of stricture in this race. The cone or dumbbell-shaped, basophilic gamma bodies and the clusters and the chains of smaller azurophilic elementary bodies have been demonstrated in cells of human lesions by Coutts et al, 1942.

Experimental Infection, Host Range

The first experimental transmission of the disease is credited to Hellerström, 1929, who infected a man by the intra-urethral route Using monkey-passage material, Wassén, 1935, infected Frei-negative patients suffering from general paralysis or dementia praecox; the lesions produced were typical of lymphogranuloma venereum

The span of the host range is still not completely known. It was the successful transmission of the virus to monkeys (*Cercopithecus callithrix*) and the mouse that greatly accelerated knowledge of the disease, its etiologic agent and methods of diagnosis These two are the most highly susceptible animals, less susceptible are the guinea pig, rabbit, squirrel, marmot, harvest mouse, rat, cat, dog and sheep Results have been erratic in experimental infection of the less-susceptible animals. Young rats, guinea pigs and rab-

apparently does not intensify the cutaneous sensitization.

The Frei test usually becomes positive 7 to 40 days after onset of the adenitis. The rare false negative Frei reaction is usually due to such factors as the menses, septicemia, fever, tuberculosis or coexistent early syphilis or early chancroid. *If the clinical picture* suggests early infection, the Frei test should be repeated. In a study of 1,265 patients, 243 gave persistently positive reactions, and all but 17 of the 243 gave a history typical of infection or showed clinical manifestations (Connor et al., 1937). The best available clinical and experimental information suggests that the reaction usually becomes positive 1 *to 6 weeks after* the infection begins and probably remains so for the life of the patient (Palmer et al., 1942). The specificity of the test has been doubted because it has been positive in patients without a history or clinical evidence of lymphogranuloma venereum and especially in patients suffering from syphilis (Robinson, 1940). In the clinical cases, the specificity is now considered to be of a high order, and the results closely parallel those of the complement-fixation test, using yolk-sac antigen in both. In viral pneumonia caused by other members of the psittacosis-lymphogranuloma venereum group the intradermal test with *Lygranum* or a similar preparation with a psittacosis virus may be positive. Furthermore, in occasional cases of lymphogranuloma venereum diagnosed on clinical grounds the intradermal test has been strongly positive but the complement-fixation test negative. Specific antigen prepared by acid extraction of elementary bodies give reactions only in patients infected with lymphogranuloma venereum. Successful treatment early in the infection may reverse the cutaneous sensitivity (Koteen, 1945). Under cortisone therapy the allergic reaction may temporarily disappear, while the complement-fixation reaction remains positive.

4. Propagation of the virus in the yolk sac or the lungs furnishes potent antigens for use in the complement-fixation test. Since the heat-stable group antigen is the active component of the reagent, it has been suggested that the enzootic abortion virus, which is safe to handle and grows to a higher titer, be used (Dane, 1955). In Heyman's study (1946), all of 27 patients with early lymphogranuloma venereum, proved by isolation of the agent, had complement-fixation titers of 1:40 or more, and most had titers of 1:160 or higher. The geometric mean titer in 45 symptomatic and asymptomatic persons was 1:80 (Greaves and Taggart, 1953). However, more *important than the height of the titer is the* serologic trend determined by study of acute phase and convalescent serum collected over a period of weeks. A single positive complement-fixation reaction as a rule is not sufficient basis for a serologic diagnosis. The serum of patients who have recovered from psittacosis may give a positive complement-fixation reaction with lymphogranuloma venereum antigens. *Patients suffering from* lymphogranuloma venereum or psittacosis give low-titer complement-fixation reactions with an antigen prepared from conjunctival scrapings of patients suffering from well-developed trachoma. On the other hand, positive complement-fixation tests with serum of trachoma patients in the presence of psittacosis or lymphogranuloma venereum antigen are rare and of low titer (Babudieri et al., 1955). The ability of the serum of lymphogranuloma venereum patients to react with the psittacosis antigen may be removed by absorption of the group antibody with steamed lymphogranuloma venereum virus (Bedson et al., 1949). This somewhat laborious procedure leaves the major part of the antibody intact, the absorbed serum gives a specific complement-fixation reaction with unheated lymphogranuloma venereum virus, but not with the psittacosis virus. The complement-fixation test serves as a useful instrument for screening population groups and for gauging the incidence of lymphogranuloma venereum, it has special utility in epidemiologic studies because it can be performed concomitantly with a serologic examination for syphilis.

It is quite apparent that no relation exists between the titers of the complement-fixation test and the intradermal test in symptomatic or asymptomatic lymphogranuloma. It is reported that in 54 to 62 per cent both reactions are positive (Greaves and Taggart, 1953). Of 1,119 patients in a venereal disease clinic, 206 (18.4%) gave positive Lygranum skin tests, while only 24 (2%) had complement-fixation antibodies in titers high enough

lymphogranuloma venereum species-specific antigen of the same character as the parakeet psittacosis antigen (Ross and Gogolak, 1957). This has not been tried.

An attack of lymphogranuloma venereum probably induces a lasting immunity (Koteen, 1945). An infected person is fully refractory to a cutaneous or intradermal reinfection with material proved to contain the virus; a local reaction similar to that induced by inactive virus (Frei reaction) develops at the site of insertion, but neither the skin nor the regional lymph nodes show signs of infection. Whether or not the immunity survives the disappearance of the virus from the host has not been determined. Prolonged coexistence of infection and immunity is characteristic of this group of agents. Consequently, clinical relapses have been reported and may be anticipated. A fairly large percentage of completely recovered experimental animals have been immune to intranasal or intracerebral reinfection

There is evidence that injection of inactivated preparations leads to the development of immune bodies and resistance to moderate infection There are no records of human immunization with vaccines.

Reports are contradictory regarding the production of neutralizing antibodies Negative results are attributable to the use of faulty technics, such as too short incubation of virus-serum mixtures or use of serum dilutions in the presence of concentrated viral suspensions. Hyperimmunization of chickens (Hilleman, 1945) with yolk-sac suspensions invariably produces potent neutralizing antiserum which has protective, toxin-neutralizing, agglutinative and complement-fixation inhibiting properties. Such serum conveys no cross protection against infection with any other member of the group. The serum of guinea pigs, rabbits, mice or rats immunized with this virus gives strong complement-fixation reactions with the homologous antigen, and frequently an equally marked reaction will occur with heterologous antigens prepared with other members of the group The complement-fixation test indicates a broad antigenic similarity between the members of the group; however, unexplained differences in titer are on record (Smadel et al., 1943).

Diagnosis

Lymphogranuloma venereum must be differentiated from chancroid, bubo due to pyogenic lesions of the lower extremities, tuberculosis of the inguinal lymph nodes, gonorrhea, syphilis, granuloma inguinale, balanitis, plague, tularemia, carcinoma and tuberculosis of the rectum, and ulcerative colitis.

1. Films of pus should be examined for organisms, and cultures should be prepared aerobically and anaerobically, not omitting the rabbit blood technic for Ducrey's bacillus If organisms are not found it is advisable to make special examinations

2. Biopsy material should be collected, and smears of bubo pus or even tissue sections are stained with Giemsa or Noble stain for the demonstration of the elementary bodies Unfortunately, histologic examinations are not commonly made Changes in chancres and lymph nodes are characteristic enough to distinguish them quite accurately from similar lesions of other venereal diseases Material from genital lesions should be subjected to darkfield examination.

3 The intradermal test of Frei (1925) is used extensively as a practical test It consists of intradermal injection of 0.1 ml. of antigen and 0 1 ml of control material. The test is read 48 and 96 hours after injection A raised papule measuring 6×6 mm. or greater indicates a positive reaction if the papule produced by the antigen control is 5×5 mm or smaller. Originally, the Frei antigen was prepared by diluting fresh pus or pus dried from the frozen state from the bubo of a known human infection with 5 times its volume of sterile saline solution Then it was sterilized by heating at 60° C for 2 hours on one day and for 1 hour on the next In antigens prepared from infected monkey or mouse brain, although specifically effective if properly controlled, the virus content was frequently low and reactions doubtful. A satisfactory antigen can be prepared from the yolk sacs of chick embryos moribund or recently dead from infection (Rake et al, 1940). Control material is prepared from the normal yolk sac of 10-day chick embryos The skin test material is known commercially as Lygranum Positive reactions to yolk-sac antigens remain readily visible and palpable for 10 days and longer, and repeated testing

(Luger, 1950). This high incidence is not indicative of any known racial predisposition; several factors in the unhygienic environment probably influence the occurrence of larger numbers of cases. In London, of the 23 patients in a venereal disease clinic with strongly positive complement-fixation reactions, 14 were Caucasian, 9 were Negro. Two per cent of completely asymptomatic patients apparently had latent infection (King et al, 1956). The idea that the infection is very rare in the Nordic countries deserves reconsideration and broader epidemiologic investigations in the light of these findings and the demonstration of positive complement-fixation reactions with antigens made with members of the psittacosis-lymphogranuloma venereum group in persons with no proved contact with avian reservoirs.

Control Measures

Modern plans for combating syphilis and gonorrhea, emphasizing as they do case finding and medical care and control of infected persons, are applicable to lymphogranuloma venereum. The first step is to make the infection reportable. Adequate diagnosis, including the complement-fixation test, must be made available through local health departments. Since serologic examinations are less expensive and more readily carried out, in the routine examination of sexually promiscuous persons the complement-fixation test should be used. The city health department should provide, free of charge, drugs for treatment. Early intensive treatment of clinical and subclinical infections should be assigned to private physicians or special clinics. Public education and the information of physicians of developments in diagnosis and treatment are other important steps.

to justify the diagnosis of active infection (King et al, 1956). Occasionally, antibodies may be detected in the serum of patients a month after infection, sometimes before the Frei reaction becomes positive The reaction probably remains positive as long as virus is still present in the host. The complement-fixation test is unsatisfactory as an index of the therapeutic effect of drugs. Patients with tertiary lymphogranuloma venereum continue to maintain circulating complement-fixing antibodies even after clinically satisfactory antimicrobial therapy. Diminishing complement-fixing antibody titers cannot be used to establish a retrospective diagnosis even after clinically successful treatment with broad spectrum antimicrobial drugs (Goldberg and Banov, 1956) A Wassermann or Kahn test should always be done; the incidence of biologically false positive serum tests for syphilis in lymphogranuloma is overestimated (Simpson, 1954)

5 Animal experiments used for isolation and identification of the infective agent are experimental rather than practical procedures Suspected material may be inoculated into the yolk sac of an embryonated hen's egg, but intracerebral inoculation of mice is preferred because diagnosis can be made 5 to 15 days earlier Furthermore, the rodents are fairly resistant to infection by bacteria occasionally contaminating specimens of bubo pus or biopsy material Identification of the virus is based on its appearance, the fact that it is more likely to cause disease by the intracerebral than by the intraperitoneal route and its susceptibility to sulfonamides The virus is regularly present in pus from buboes and is more often isolated from tertiary than from primary lesions, even up to 21 years after infection It has been found in the blood, in the spinal fluid in meningeal infection and in the stool of patients with proctitis

Treatment

The results of treatment with sulfonamides have been good, but the serious side-effects have placed an obstacle in the way of their prolonged use. Penicillin, active against experimental lymphogranuloma, proved to be ineffective clinically in the dosages employed. Tetracyclines are effective against experimental infection, and reports on the therapeutic value of chlortetracycline or oxytetracycline in human beings during the early stage of infection were at first enthusiastic, but later ones have been more reserved. Subjective improvement is noted, and patients may be clinically cured in spite of persistence of the virus in the body. For long-standing disease, 500 mg. 4 times a day is recommended The individual dose may be reduced later to 250 mg. and continued for 3 to 6 weeks for early infections and for longer periods for more advanced infections Chlortetracycline is claimed to be less effective than oxytetracycline (Henley, 1953). In spite of long-standing disease, form and function may be remarkably restored. Conversely, treatment may not be wholly effective even in early lymphogranuloma.

Epidemiology

This disease in all probability is of almost world-wide distribution (Favre and Hellerstrom, 1954), but since it is reportable in only a few places there is no way of knowing its prevalence. The deficiency is not imputable to administrative procedure alone, the disease has been poorly reported because satisfactory diagnosis has not been available. The prevalence in tropical countries and in the Mediterranean, southern and eastern ports is less a matter of climate than of unfortunate social conditions Although most of the patients in reported cases have been men, there is no apparent reason why women should not suffer from this infection in about the same

fected in the course of surgical removal of infected lymph nodes, and hospital orderlies have become infected while bathing patients

In the United States there [redacted] no scarcity of cases in clinics and hospitals The disease is reportable in only Alabama, California, Illinois and Washington The greatest number of cases are reported from areas east of the Mississ

Trachoma and Inclusion Conjunctivitis

INTRODUCTION

Trachoma and inclusion conjunctivitis are closely related but distinct viral infections of the external eye, often similar in clinical appearance in their early stages but differing widely in clinical course and economic importance Trachoma has a world-wide distribution, rarely heals spontaneously, invariably *involves the cornea and usually* leads to visual disability from conjunctival and corneal cicatrization Inclusion conjunctivitis never involves the cornea or produces scars, is always self-limited and never has been found in certain populations Moreover, trachoma affects the eye only, whereas inclusion conjunctivitis, *seen most often as one type of ophthalmia* neonatorum, is the ocular manifestation of a benign nongonococcal urethritis and cervicitis

In spite of these important differences, the two diseases have often been confused because of the morphologic identity of their inclusion bodies and because follicular hypertrophy of the conjunctiva is a prominent clinical sign in both These similarities, both clinical and etiologic, have influenced investigators to study the two infections simultaneously, hence their consideration in the same chapter in the present volume

TRACHOMA

(SYNONYM Granular conjunctivitis)

HISTORY

Trachoma was an affliction of antiquity and one of the first disease entities to be described [illegible]

cedures (grattage, scarification of follicles, and application of copper salts) that have been in use until recent times Trachoma was common in ancient Rome and is known to have afflicted Cicero, Horace and Pliny the [illegible]

out Europe

Of all ocular affections, trachoma has always been the one of greatest world-wide economic and social consequence It is the only eye disease in whose interest special hospitals and research institutes have been established the world over; to which a special journal, the *Revue Internationale du Trachome*, is devoted, and toward whose eradication the World Health Organization has instituted an Expert Panel and sponsored a series of mass treatment campaigns. Several of these are presently under way in a number of countries, but in spite of their partial success the disease is still a major affliction throughout the world

The highest incidence of trachoma prevails in North Africa, Egypt and the Middle East where the majority of the population is still affected It is also widespread in all the other Mediterranean countries, as well as in the Balkans, in Russia and throughout the Orient In North European countries it has almost

Trachoma and Inclusion Conjunctivitis

INTRODUCTION

Trachoma and inclusion conjunctivitis are closely related but distinct viral infections of the external eye, often similar in clinical appearance in their early stages but differing widely in clinical course and economic importance Trachoma has a world-wide distribution, rarely heals spontaneously, invariably involves the cornea and usually leads to visual disability from conjunctival and corneal cicatrization Inclusion conjunctivitis never involves the cornea or produces scars is always self-limited and never has been found in certain populations Moreover trachoma affects the eye only, whereas inclusion conjunctivitis, seen most often as one type of ophthalmia neonatorum, is the ocular manifestation of a benign nongonococcal urethritis and cervicitis

In spite of these important differences, the two diseases have often been confused because of the morphologic identity of their inclusion bodies and because follicular hypertrophy of the conjunctiva is a prominent clinical sign in both These similarities, both clinical and etiologic, have influenced investigators to study the two infections simultaneously, hence their consideration in the same chapter in the present volume

TRACHOMA

(SYNONYM Granular conjunctivitis)

HISTORY

Trachoma was an affliction of antiquity and one of the first disease entities to be described

ease and the 3 principal therapeutic pro-

out Europe

Of all ocular affections, trachoma has always been the one of greatest world-wide economic and social consequence It is the only eye disease in whose interest special hospitals and research institutes have been established the world over, to which a special journal, the *Revue Internationale du Trachome*, is devoted, and toward whose eradication the World Health Organization has instituted an Expert Panel and sponsored a series of mass treatment campaigns Several of these are presently under way in a number of countries, but in spite of their partial success the disease is still a major affliction throughout the world

The highest

Balkans, in Russia and throughout the Orient. In North European countries it has almost

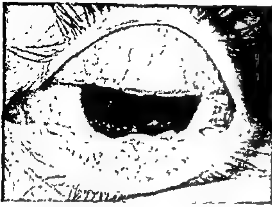

FIG 116 Trachoma, Stage I, in an Indian child, showing follicular hypertrophy of the conjunctiva.

disappeared. In the United States it is still prevalent among the Indians and has in fact recently been recrudescent, particularly among the tribes of the Southwest In the white population of the United States it used to flourish among the mountain people along the so-called "Daniel Boone Trail" across the Appalachians, but the incidence in this group has steadily decreased. Sporadic cases are seen elsewhere in the country, especially among immigrants in the form of reactivations of old cicatricial disease.

In 1907 Halberstaedter and Prowazek found the elementary bodies and the cytoplasmic inclusions that characterize the disease, and in 1910 Lindner described the initial-body form of the virus. In 1912 Nicolle et al. reported the first positive filtration experiments which they accomplished with modified Berkefeld V filters on *M. sylvanus* monkeys. In 1935 Thygeson et al. performed a human inoculation experiment with trachomatous material filtered through a gradocol membrane of 0.6 micron average pore diameter and found that infectivity was associated with the presence of elementary bodies in the filtrate Subsequent investigators noted the many resemblances of trachoma virus to the viruses of psittacosis and lymphogranuloma venereum On this basis it was classified by Bedson and Rake, along with inclusion conjunctivitis virus, as a member of the psittacosis-lymphogranuloma group

Trachoma virus studies have been greatly handicapped by the fact that so far it has been impossible to cultivate the virus in series or in quantity in tissue culture or in the chick embryo,* and by the fact that the only susceptible animals (monkeys, baboons and apes) develop a self-limited chronic follicular conjunctivitis which lacks the diagnostic pannus and cicatrization of the human disease. The recognition in 1938 by Loe and others that trachoma was susceptible to the sulfonamides marked the first major advance in therapy since the time of Hippocrates

CLINICAL PICTURE

The incubation period of trachoma, as determined from experimental human inoculations, is from 5 to 7 days. The onset is usually insidious, particularly in children, but it may be acute, depending apparently on the amount of inoculum. The onset in adult infections and experimental infections has almost always been acute and has sometimes been fulminating, with chemosis of the bulbar conjunctiva and copious exudate. The more common childhood disease may be extremely mild in its early stages Indeed, it may present no gross signs whatever beyond perhaps a slight ptosis; however, when the lids are everted, a characteristic follicular hypertrophy (Fig 116), most marked on the upper tarsal conjunctiva, is to be seen In these early cases biomicroscopic examination is required to detect the corneal signs of the disease which include epithelial keratitis, subepithelial infiltration and extension of limbal vessels (pannus) In cases with acute or subacute onset, the follicles are often masked by intense papillary hypertrophy of the conjunctiva, but the corneal changes (edema of the upper limbus, subepithelial infiltration, pannus) appear early and are conspicuous This acute stage, with its abundant exudate, lasts for several weeks and is followed by a chronic stage of variable intensity; the exudate dwindles to a minimum (unless there is secondary infection), and the symptoms of irritation subside

Whether the onset has been insidious or acute, the disease progresses in much the same way over a period of months or years to conjunctival and corneal cicatrization, except that trachoma contracted early in life, as is the rule in such heavily infected areas as Egypt and the Middle East, tends to be a milder disease and to heal spontaneously more often. The degree of cicatricial change varies greatly, but lid deformities, including ptosis, trichiasis and entropion, are common, and in old cases visual disturbance from corneal scars is almost the rule In unusually severe cases

* See footnote page 733

cicatrization may destroy tear function, then keratitis sicca, with keratinization of the corneal epithelium, may ensue. Secondary bacterial infection, so common in the Middle East, may further increase corneal ulceration, and vision may be totally lost Since no immunity develops in trachoma, reinfection of healed cases occurs and is a major problem in heavily infected countries.

Pathologic Picture

The earliest recognizable pathologic sign of trachoma is the characteristic cytoplasmic inclusion body in conjunctival and corneal epithelial cells (Wilson, 1937) This is followed by subepithelial infiltration with small

Advanced stages are characterized by cell necrosis and finally by cicatrization All the pathologic changes in trachoma affect the upper half of the conjunctival sac and the cornea more prominently than the lower half

Although mononuclear cells dominate the subepithelial infiltration, the exudate is composed chiefly of polymorphonuclear cells This is particularly true in the acute stages of the disease and in no way depends on secondary bacterial infection In contradistinction, the exudates of conjunctival infections with typical viruses, such as the adenoviruses and the herpes simplex virus, are characteristically mononuclear.

The inclusion bodies vary in number according to the clinical severity of the disease and are most numerous in scrapings from the upper tarsal and the upper limbal regions, i e, from the areas of maximum disease intensity They are most abundant in the superficial layers of the epithelium, are rare in the basal layers and never occur in follicle cells or in the subepithelial layers

Experimental Infection, Host Range

The only experimental animals susceptible to trachoma virus are, in the order of their susceptibility, apes, baboons and monkeys Unfortunately, none of these animals develops pathologic changes characteristic of human trachoma, i e, pannus and cicatrization. Moreover, the experimental disease they do develop is self-limited and appears only as a follicular conjunctivitis which cannot be differentiated with certainty from the follicular conjunctivitis produced by inclusion conjunctivitis virus, or even from the spontaneous folliculosis with which monkeys, baboons and apes are frequently affected (Wilson, 1930, Bland, 1945) The inclusion bodies characteristic of trachoma have been found regularly in the experimental disease in apes, exceptionally in the disease in baboons and never in the disease in monkeys This paucity of inclusions is believed to be due to the mildness of the experimental disease in which there are minimal inflammatory signs and exudate However, that the disease is actually trachoma has been established by Nicolle et al. 1912 and by Bland (1944) These workers succeeded in transferring the experimental disease from its animal hosts to human volunteers who in turn developed typical trachoma

Experimental infection in human beings has been achieved on numerous occasions, usually with an acute onset and abundant inclusions No immunity to reinfection has developed in either human or animal hosts

Etiology

The cause of trachoma is a virus of large particle size resembling the viruses of psittacosis and lymphogranuloma venereum in staining properties, particle size, intracellular cycle of morphologic variation, and susceptibility to sulfonamides and antibiotics. Its elementary bodies measure about 0 25 micron in diameter in Giemsa-stained preparations They are to be seen in conjunctival and corneal epithelial cells in colony form (the inclu-

cells exclusively It undergoes an intracellular cycle of morphologic variation in which the young forms (the initial bodies) are larger, typically oval, stain bipolarly a pure blue with Giemsa, and occur in colony form as initial body inclusions (Fig 117B) In wet-fixed slides or free in the exudate the initial bodies vary in size from 0.3 to 1 2 microns and exhibit typical division forms Mitsui and Suzuki (1956) have studied them under the electronmicroscope (Fig 118) and noted their lesser density as compared with the density of the elementary bodies. While not denying their division by binary fission, these

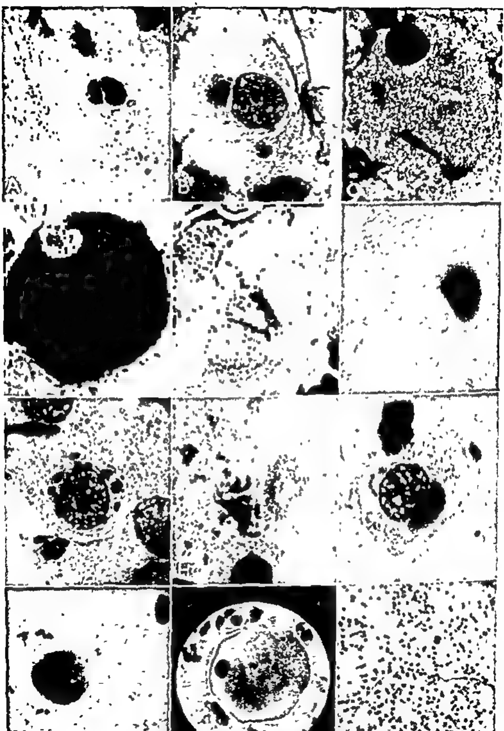

FIG. 117 (A) Free elementary bodies in the exudate from a case of severe trachoma. Giemsa stain $\times 1500$.
(B) Young inclusion bodies made up of large swollen forms, the so-called initial bodies of Lindner. Giemsa stain. $\times 1500$. (*Continued on facing page*)

observers have suggested the possibility of an alternate vegetative process of reproduction

The inclusion body is a virus colony in which the elementary and initial bodies are embedded in a carbohydrate matrix composed principally of glycogen (Figs. 117C-F) (Rice, 1936). The evolution of the inclusion body in a susceptible cell requires about 48 hours Multiple infection of cells is common (Fig 117G) The existence of a toxin is suggested by the following facts (1) toxins have been demonstrated for other members of the psittacosis-lymphogranuloma venereum group of agents (Rake and Jones, 1944), (2) in the experiment of Mitsui, et al (1954), repeated instillations of a virus-free ultrafiltrate of trachomatous material produced follicular hypertrophy of the conjunctiva of a volunteer; and (3) important subepithelial changes occur in trachoma even though the virus appears to be limited strictly to the epithelial layer In this connection it is noteworthy that attempts to infect the subepithelial layers of the conjunctiva by injecting trachoma virus through the skin of the lids failed, and that subsequent direct inoculation of the conjunctiva of the same subjects succeeded (Michail and Vancea, 1932).

The virus is rapidly inactivated by bile and by drying, by alternate freezing and thawing and by incubator temperature (37° C.). Its thermal death point is 45° C maintained for 15 minutes (Julianelle, 1938) At refrigerator temperature, or in 50 per cent glycerol, it can be preserved for as long as a week. Sulfanilamide has no virucidal effect in vitro (Julianelle and Smith, 1942). Attempts to cultivate the virus in tissue culture in quantity or in series have been unsuccessful, even when cultures of human conjunctival and corneal epithelium have been used Trachomatous conjunctival epithelium has rapidly lost its infectivity for baboons when grown in tissue culture (Thygeson, 1939) There are numerous claims for cultivation of the virus in the yolk sac and the chorioallantois of the developing chick embryo (Macchiavello, 1944, Poleff, 1949, Stewart and Badir, 1950), but cultivation in series or in quantity on these membranes has certainly not yet been achieved.* Low titers of group

* Since the preparation of this chapter, cultivation of trachoma virus in series on the yolk sac of the developing chick embryo has been claimed by Tang, F F, Chang, H L, Huang, Y T, and Wang, K C Studies on the etiology of trachoma with special reference to isolation of the virus in chick embryo (Chinese M J, 75, 429-447, 1957) and confirmed by Collier, L H, and Sowa, J, Isolation of trachoma virus in embryonate eggs (Lancet, 1, 993-996, 1958) Collier and Sowa produced trachomatous infection of a human volunteer with the yolk-sac-cultivated material and recovered characteristic inclusions and elementary bodies from the experimental disease

complement-fixing antibodies for the psittacosis-lymphogranuloma venereum group have been demonstrated in sera from trachoma patients by Rake et al (1942), but there is no evidence to suggest that they are concerned in the clinical course of the disease or in developing immunity to it. Monkeys and baboons that have recovered from experimental trachoma show no immunity to reinfection, and the second infection runs the same clinical course as the first.

The virus filters with difficulty and only through such coarse filters as the Berkefeld V candle and gradocol membranes of 0 6 micron A P.D. or above. If an active filtrate is to be obtained, the elementary bodies must pass the filter. This was demonstrated in the experiment of Thygeson et al. (1935) in which a human volunteer was inoculated successfully with a gradocol filtrate (0 6 micron A.P.D.) The original material, consisting of ground epithelial scrapings from trachomatous Indian children, contained abundant inclusions Elementary bodies were demonstrated in the bacteria-free filtrate after centrifugation, and inclusion bodies were numerous in the experimental disease at onset.

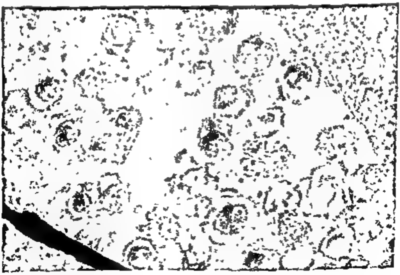
Diagnosis

Trachoma can usually be diagnosed on the basis of the following clinical signs (1) follicle formation, most prominent on the upper tarsal region, (2) trachomatous pannus, which can be recognized in its incipience early in the disease on slit-lamp examination of the upper limbal region, and (3) conjunctival cicatrization

Laboratory diagnosis is based on the demonstration of cytoplasmic inclusion bodies and on certain cytologic changes in expressed follicular material Although the inclusions are morphologically identical with those of inclusion conjunctivitis, in trachoma they are more numerous on the upper tarsal conjunctiva than on the lower, and in inclusion conjunctivitis they are more numerous on the lower tarsal conjunctiva than on the upper (Braley, 1940). In expressed follicular material from trachoma, necrotic changes not found in other follicular diseases of the conjunctiva are to be seen in the form of cell debris, pale-staining cells, and numerous macrophages loaded with cell fragments (Thygeson, 1946).

Treatment

Prior to the introduction of sulfonamide therapy in 1938, trachoma was treated by a combination of medical and surgical means Medical treatment consisted in the control of secondary infection by antiseptic drops, and in the application to the conjunctiva of caustics, such as copper sulfate, silver nitrate,



... section show-

quinine bisulphate, etc. Surgical treatment consisted in the correction of cicatricial deformities, such as entropion and trichiasis, and in the removal of diseased conjunctiva by tarsectomy The inadequacy of these measures is indicated by the fact that few patients tolerated treatment sufficiently long to obtain relief and that the few cures obtained took from one to many years of continuous medical care

Under sulfonamide therapy the prognosis of trachoma has changed entirely In early cases cures can now be expected in a matter of weeks No sulfonamide resistance has ever been observed As in the related disease, lymphogranuloma venereum, low dosages and relatively prolonged treatment times (2 to 4 weeks) are required. In the cicatricial stages sulfonamide therapy is less satisfactory, and surgical intervention for the relief of cicatricial complications may be required Prognosis is poorest in those cases in which tear-function has been lost and in cases complicated by vernal catarrh or secondary bacterial infection

The broad-spectrum antibiotics (chlortetracycline, chloramphenicol and oxytetracycline) have all shown antitrachomatous activity (Mitsui et al, 1951, Bietti, 1951) When used orally, their effect has been comparable with that of the sulfonamides, but when used topically they appear to be more efficacious than topically administered sulfonamides

Epidemiology

In the countries of the Middle East, such as Egypt, trachoma is commonly acquired in the first year of life, usually from the mother When periodic epidemics of the acute ophthalmias occur, it is often transmitted simultaneously with the bacterial infections (Wilson, 1930) In countries in which the disease is only endemic, as in the United States, spread occurs only when there is constant exposure to infection under conditions of poor hygiene such as formerly obtained among the mountain folk of West Virginia, Kentucky and Tennessee and still prevail in some of our Indian populations

On the basis of the virus content of epithelial scrapings, it may be assumed that acute cases are highly infectious and chronic cases only slightly so In sporadic cases it is often impossible to trace the source of infection, but it is believed that eye-to-eye transmission by means of fingers or fomites is possible and that the fly may play an important role (Wilson, 1930) So far no evidence to indicate the existence of a subclinical infection or carrier state has been advanced

Control Measures

The control of trachoma in the countries in which it is pandemic devolves chiefly upon the control of the acute ophthalmias (Wilson, 1945) This is now theoretically possible by means of chemotherapy but on practical grounds is limited by lack of funds, the countries in which trachoma is widespread being the ones most economically depressed Since trachoma is a disease of filth and poor personal hygiene, all measures leading to improvement in the economic condition of the population exert a prophylactic effect In the United States the experience of the Division of Indian Health in its attempts to control the disease has illuminated the dramatic effect of the change in therapeutic method Prior to the introduction of the sulfonamides in 1938, the extensive antitrachoma campaign conducted in the Indian schools was only moderately successful, but when sulfonamide therapy was instituted, the incidence of the disease was strikingly reduced in short order (Forster and McGibony, 1944) However, a recent recrudescence, particularly among the Indians of the Southwest, has necessitated a revival of the diagnostic and treatment campaigns In the white population of the United States control consists in the early recognition and treatment of the disease, particularly in isolated communities of the old "trachoma belt" To this end stationary and mobile trachoma clinics have been established in Arkansas, Illinois, Missouri and Virginia

INCLUSION CONJUNCTIVITIS

(Synonyms Inclusion blennorrhea, paratrachoma, swimming-pool conjunctivitis)

History

A benign form of conjunctivitis in the newborn, unassociated with pathogenic bacteria, was described by Morax as early as 1903 Shortly after Halberstaedter and Prowazek discovered cytoplasmic inclusion bodies in trachoma in 1907, Stargardt, 1909, and then

Schmeichler, 1909, noted identical inclusions in ophthalmia neonatorum. In 1911 Lindner reported finding inclusions in all but a very few cases of ophthalmia neonatorum of nonbacterial origin He had been able to transmit the disease to the conjunctiva of the baboon and to demonstrate identical inclusion bodies in the experimental disease. He defined its clinical characteristics and named it *Einschlussblennorrhoe* (inclusion blennorrhea). In 1910 Wolfrum described two successful inoculations of human beings with inclusion blennorrhea exudate.

Searching for the origin of this disease of the newborn, Halberstaedter and Prowazek, 1909, found typical inclusions in scrapings from the genito-urinary tracts of mothers of diseased infants and postulated the existence of a genito-urinary inclusion disease of the male and the female This theory was supported by Lindner, 1910b and Heymann, 1910, who found inclusions in several cases of urethritis in the male In the same year Fritsch et al, 1910, produced a conjunctival infection in a baboon with urethral exudate from nongonorrheal urethritis containing inclusions.

The first filtration experiments were made in 1912 Botteri, 1912, induced infection in the eye of a baboon with a Berkefeld V filtrate, and Gebb, 1914, confirmed his work by obtaining infection in a human subject with a similar filtrate Subsequent filtration studies by Thygeson (1934), Tilden and Gifford (1936), and Julianelle et al (1938) showed that the virus was filterable with relative ease through coarse Berkefeld candles and gradocol membranes

Unfortunately, some confusion arose as to the relationship of the disease to trachoma and to the conjunctivitis with inclusions seen in adults, particularly in bathers in certain swimming-pools Some authors regarded this adult disease as identical with trachoma, but such a conclusion was obviated by the self-limited nature of the inclusion disease and its failure to produce pannus or cicatrization. Morax (1933) differentiated it sharply from trachoma and offered evidence, later confirmed by Thygeson (1934) and Julianelle (1937), to show that the infant and the adult types of conjunctivitis with inclusions, in spite of certain differences, were manifestations of a single disease

Thygeson and Mengert (1936) found that in mothers of babies with inclusion blennorrhea, the genito-urinary disease was limited to the external os of the cervix and to an area of transitional epithelium identical histologically with the epithelium of the conjunctiva. They reported that the infection produced no clinical symptoms in the mothers, but that in the fathers it was only occasionally subclinical and usually appeared as a mild, nonspecific urethritis of several months' dura-

to be an occupational disease of obstetricians

sponded rapidly to sulfonamide therapy, and later Thygeson and Stone (1942b) showed that topical applications of the sulfonamides were invariably successful in the treatment of the disease in the newborn

Clinical Picture

The incubation period of inclusion conjunctivitis varies from a minimum of 5 days to a maximum of 12. In the newborn the onset is acute, a purulent conjunctivitis developing rapidly with intense infiltration of the conjunctiva, particularly of the lower lid In very severe cases transient pseudomembranes are noted, and clinical differentiation from gonorrheal ophthalmia may be difficult After an acute stage, lasting from 10 days to 2 weeks, the disease gradually loses its intensity over a period of months The discharge may cease in as short a time as 2 months, but the conjunctiva rarely if ever returns to normal in less than 3 months and may show infiltration for as long as a year However, unlike trachoma, inclusion conjunctivitis never develops pannus or significant conjunctival cicatrization. It is always self-limited, and persistent chronic infections are unknown

The clinical appearance of the disease in the adult differs, often rather strikingly, from that in the newborn baby. Typically, it is an acute follicular conjunctivitis with scanty discharge and preauricular adenopathy; the follicular hypertrophy, unlike that of trachoma, is much more marked in the conjunctiva of the lower lid than in that of the upper. Occasionally, a severe infection may appear as a papillary conjunctivitis with moderately abundant exudate. In this form the adult dis-

ease more closely resembles the disease in the newborn but never exhibits the fulminating character so often seen in the latter. The adult disease tends to persist over a longer period of time, sometimes for more than a year. However, all reported cases have eventually resolved spontaneously without residual conjunctival or corneal changes.

Pathologic Picture

Examination of biopsy material from the disease in the newborn infant at onset shows an infiltration of the conjunctiva with small round cells, resulting in a many-fold increase in the thickness of the conjunctiva. The epithelium is infiltrated with polymorphonuclear cells and contains numerous basophilic cytoplasmic inclusion bodies morphologically identical with those of trachoma. The inclusion bodies are the first recognizable pathologic sign of the disease and have been demonstrated during the incubation period of experimental human infections. Biopsy material taken late in the course of the infection may show lymphoid follicles, a feature entirely lacking in the early stages.

In the adult the typical pathologic picture is a follicular hypertrophy of the conjunctiva associated with infiltration of small round cells. The follicles have the same histologic structure as those of trachoma but none of their necrotic features. Polymorphonuclear leukocytes predominate in conjunctival scrapings collected during the acute phase, but as the disease becomes chronic there is an admixture of mononuclear cells.

Experimental Infection, Host Range

Like trachoma virus, inclusion conjunctivitis virus infects only monkeys, baboons, apes and human beings. Baboons and apes are more susceptible than monkeys. Baboons inoculated with exudate develop an acute follicular conjunctivitis identical clinically with the adult human disease, but the clinical picture of inclusion blennorrhea in the newborn has never been reproduced in animals. Experimental inclusion conjunctivitis in lower animals is somewhat more intense than experimental trachoma. It is of shorter duration, and its inclusions are relatively easy to demonstrate. Otherwise, the two experimental diseases are indistinguishable. The relative intensity of experimental inclusion conjunctivitis reduces the likelihood of confusing it with spontaneous folliculosis. The cervix of the female baboon has been experimentally infected with inclusion conjunctivitis virus (Braley, 1939), but all attempts to induce experimental urethritis in the male baboon have been unsuccessful.

Etiology

The cause of inclusion conjunctivitis is a virus of large particle size morphologically identical with trachoma virus and showing the same intracellular cycle of morphologic development. No electronmicroscopic studies of it have as yet been made. It passes Berkefeld V candles, and its diameter, as determined by filtration through gradocol membranes, lies between 0.15 and 0.39 micron (Thygeson, 1934). It is destroyed rapidly by bile and by drying but can be preserved for several days in 50 per cent glycerol or at refrigerator temperature. All attempts to propagate it in chick embryo or human conjunctival tissue culture have failed. Group antibodies for the psittacosis-lymphogranuloma venereum viruses have been demonstrated in sera from patients with inclusion conjunctivitis (Rake et al., 1942).

The infectious units of inclusion conjunctivitis virus are elementary bodies with a diameter of about 0.25 micron in Giemsa-stained preparations. Masses of them can be seen as intracellular inclusion bodies (Fig. 117I), or free in the exudate in acute cases (Fig. 117H). Larger forms, first described by Lindner, 1910a, and known as initial bodies, are seen in initial-body inclusions and occasionally free in the exudate (Fig. 117J). They are apparently the forms produced when the virus first divides within the cytoplasm of susceptible cells. In the inclusion body the masses of elementary and initial bodies are embedded in a carbohydrate matrix identical with the matrix described for trachoma virus by Rice (Thygeson, 1938). According to observations made during the incubation period of experimental infections, the cycle of intracellular development requires about 48 hours. The inclusion bodies are limited strictly to the superficial layers of the epithelium (Braley, 1938). This applies also to the genito-urinary infection in the female (Fig. 117K). The existence of a toxin has been postulated to explain the subepithelial

changes that occur. The virus is not affected by sulfonamides in vitro, but the disease is rapidly cured by sulfonamide therapy. Morphologic observations indicate that the sulfonamide probably acts by preventing development of the virus in vivo rather than by killing it Topical applications of cortisone increase the susceptibility of the conjunctival and corneal cells to the virus and tend to reactivate quiescent cases.

Lindner suggested that trachoma virus and inclusion conjunctivitis virus were originally identical, that inclusion conjunctivitis virus, as a result of its sojourn on the mucous membranes of the genito-urinary tract through countless generations, eventually lost its ability to produce pannus and cicatrization, and that the two viruses bore a relationship to each other similar to that borne by the viruses of vaccinia and variola However, up to the present time no data to support this hypothesis have been submitted, and in 1944 Allen reported that inclusion conjunctivitis virus took on none of the characteristics of trachoma virus in the course of 40 serial transfers to the conjunctivas of human subjects. In this connection, Braley (1939) made the interesting observation that trachoma virus *could also produce infection of the cervix of* the female baboon

Diagnosis

The clinical diagnosis of inclusion conjunctivitis in the infant is facilitated by its delayed onset (5 to 12 days) and by the characteristic conjunctival thickening and coxcomblike appearance of the lower fornix *However, clinical diagnosis must be confirmed* by the finding of inclusion bodies Since trachoma never develops in newborn infants in the first week or two of life, the demonstration of inclusions in the infant is pathognomonic of inclusion conjunctivitis

In the adult an acute follicular conjunctivitis with mild preauricular adenopathy always suggests inclusion conjunctivitis. The absence of corneal changes is the clinical basis for differentiation from trachoma, but other forms of acute follicular conjunctivitis cannot always be distinguished clinically For the latter purpose laboratory diagnosis based on the finding of cytoplasmic inclusions is conclusive, except, of course, with respect to trachoma from which supplementary differentiation on clinical or cytologic grounds must be made. As noted above, the expressed follicular material from trachoma shows necrotic changes never seen in follicular material from inclusion conjunctivitis

The group antibodies for the psittacosis-lymphogranuloma venereum group of viruses that have been reported have no diagnostic significance in inclusion conjunctivitis

Inclusion conjunctivitis is the most important type of nongonococcal ophthalmia neonatorum, and clinical laboratories in all hospitals should be able to diagnose it, particularly in view of the serious social consequences which may result from confusing it with gonococcal ophthalmia For this purpose epithelial scrapings should be prepared instead of the exudate films used for determining bacterial infections.

Treatment

Prior to the introduction of the sulfonamides, no form of therapy had had any effect on inclusion conjunctivitis However, sulfonamide therapy is highly successful and may effect a clinical cure in as short a time as 5 days. Topical sulfonamide therapy, usually *employed 6 times* daily over a period of 10 days in the form of 5 per cent sulfacetamide or sulfadiazine ointment, has been uniformly successful in the newborn infant and irregularly successful in adults. Its lesser efficacy in adults is probably due to the dilution of the ointment by tears, a negligible factor in newborn infants whose tear-function is minimal in the first few weeks of life However, *oral administration* of the sulfonamides has been invariably successful in adult cases, and relapses almost never occur. No instance of a *sulfonamide-resistant* viral strain has as yet been reported. Secondary bacterial infection is not a problem.

Penicillin has not been effective in the treatment of inclusion conjunctivitis (Thygeson, 1947) but medium- and broad-spectrum antibiotics have been used successfully in ointment form.

Epidemiology

Eye-to-eye transmission of inclusion conjunctivitis is extremely rare, and no epidemics have been traced conclusively to ocular infec-

tion. The epidemiology is believed to parallel that of gonorrheal ophthalmia as it occurs in the United States and Europe The genito-urinary disease, like gonorrhea, serves as a reservoir from which infection of newborn eyes occurs during childbirth, and from which sporadic adult infections develop as a result of accidental transfer of genito-urinary exudate to the eye In all probability the eye disease would cease to exist if it were not for the genito-urinary reservoir of virus Doctors and nurses dealing with newborn infants and gynecologic conditions have been accidentally infected with inclusion conjunctivitis (Thygeson and Stone, 1942a), just as they have been accidentally infected with gonorrheal ophthalmia. Swimming-pool infection was a problem before chlorination was introduced, the virus being transmitted through the water from the genito-urinary tract to the eye, in fact, cases are still being reported from small lakes and unchlorinated pools Figure 117L shows the extraordinary number of virus elementary bodies that can be found in scrapings from the cervix and indicates what an abundant source of contamination the genito-urinary tract can be

The recent drop in the incidence of the disease may very well be due to the effect on the genito-urinary tract of the widespread use of sulfonamides and antibiotics in the treatment of other infections

Control Measures

Control measures parallel those applicable to the control of gonorrheal ophthalmia, except that the Credé silver-nitrate prophylaxis does not prevent inclusion blenorrhea The intracellular habitat of the virus no doubt serves to protect it from the action of the caustic Penicillin used as a substitute for silver nitrate has been no more effective Control of swimming-pool infection would seem to depend upon proper chlorination In a survey of university swimming-pools, all properly chlorinated, Thygeson and Stone (1924a) found no instance of infection This was in sharp contrast with the large number of cases known to have been contracted in unchlorinated pools.

Strict adherence to hand-washing precautions is sufficient to prevent transfer of the infection from a patient with the ocular disease to his attendants In nurseries, however, careful isolation should be enforced to prevent transfer from infant to infant

CLASSIFICATION

Although the agents of trachoma and inclusion conjunctivitis possess the essential properties of viruses (filterability, inclusion body formation and obligate cell parasitism), they are set apart from the typical large viruses, such as vaccinia virus and fowlpox virus, by a number of distinguishing properties These include their susceptibility to chemotherapy, the basophilic character of their inclusion bodies, and their intracellular cycle of morphologic variation

The similarity of the tinctorial and morphologic properties of the agents of trachoma and inclusion conjunctivitis to those of psittacosis virus was noted by Thygeson in 1934 and later stressed by Bedson and by Rake and Jones In 1938 Findlay, MacKenzie and MacCallum postulated an intracellular cycle of morphologic development for the elementary bodies of trachoma analogous to that described by Miyagawa and his associates for the elementary bodies of lymphogranuloma venereum Morphologically similar agents with the same tinctorial properties have since been isolated from mice, cats and calves

All these agents have the following important properties in common (1) they are relatively large and filter with difficulty, (2) they pass through an intracellular cycle of development from elementary body to initial body to elementary body, (3) they stain with simple basophilic dyes, (4) their colony form is a large, basophilic, cytoplasmic inclusion body, (5) they have common antigenic components that are demonstrable by the complement-fixation test, and (6) they are susceptible to certain antibiotics and sulfonamides Although differing among themselves in other respects and in their disease-producing potential, they would seem undeniably to form a transitional group between the typical large viruses and the rickettsiae

In 1945 Moshkovsky proposed the family name *Chlamydozoaceae* for the whole group, and the genus names *Miyagawanella* for the psittacosis-lymphogranuloma venereum agents, and *Chlamydozoon* for the agents of trachoma (*Chlamydozoon trachomatis*) and inclusion conjunctivitis (*Chlamydozoon oculogenitale*) This classification was accepted by Rake for inclusion in *Bergey's Manual of Determinative Bacteriology* in

1948 It has been protested by Meyer and Bedson but is widely employed at present, pending possible revision by an appropriate international taxonomic authority.

Measles

(SYNONYMS Morbilli, rubeola,* *rougéole,* Masern, sarampion)

INTRODUCTION

Measles is one of the important exanthemata The morbidity rate is very high, and by adult age, in denser centers of population, almost everyone has had the disease It is characterized by a prodromal period with fever, catarrh and cough, and exanthem in the mouth (Koplik's spots) Later there is a characteristic rash The prognosis, in the uncomplicated disease, is good, and even the complications, other than encephalitis, do well with modern chemotherapy

HISTORY

Measles was recognized as an independent disease by Sydenham in the 17th century, but the separation of it, perhaps with other exanthemata, was achieved by the Arabic physicians in the 9th century They considered it a milder form of smallpox It has appeared in epidemic form wherever man has established community life, and epidemics of particular severity have occurred when the virus has been introduced to a virgin soil, with the appearance of a very virulent strain (as in black measles in London, 1763-1768), or when accompanied by bacterial trailers (as in U S Army camps during World War I) Home in 1758 apparently transmitted the disease to 7 of 15 volunteers by placing cotton soaked with fresh blood of patients with florid disease in skin incisions of individuals with no previous history Hektoen, 1905, first achieved unequivocal transmission of measles to volunteers, after an incubation period of 11 to 13 days, by subcutaneous injection of blood taken within 30 hours after appearance of rash Anderson and Goldberger (1911) first transmitted measles to animals—macaque monkeys Plotz, 1938, cultivated the virus in chick cells, and Rake and Shaffer, 1939, described its cultivation in the embryonated chicken egg Enders and Peebles (1954) cultivated the virus in human post-nasal tissues and obtained typical cytopathogenic changes The prevention of the disease by inoculation of human serum containing neutralizing antibodies was first described by Nicolle and Conseil, 1918

CLINICAL PICTURE

The incubation period of the natural disease up to the appearance of the exanthem is from 12 to 19 days, usually exactly 14 days Following deliberate inoculation experiments, the incubation may be several days shorter, perhaps because the infecting doses used were larger than occur naturally However, the appearance of the typical exanthem is preceded by 1 to 5 days of prodromal symptoms, and the incubation period until the appearance of these is from 5 to 9 days

* Rubeola, unfortunately, is used as a synonym for both measles and rubella

1948. It has been protested by Meyer and Bedson but is widely employed at present, pending possible revision by an appropriate international taxonomic authority.

Warthin and Finkeldey who described these cells independently in 1931 were not the first to note them. They were described by Ciaccio in 1910 and by Alagna in 1911 These cells occur as early as 5 days after exposure to infection (that is, before any symptoms) and they persist until after the rash has appeared They appear to arise from lymphocytes, but how is not clear.

Koplik's spots are focal exudations of serum and endothelial cells into submucous glands which form vesicles by necrosis of the basal epithelium The exanthem, according to the more recent work of Torres (1952), starts as a necrosis of a few epidermal cells Within 12 hours an exudation of serum occurs around the superficial vessels in the corium and proliferation of endoth...

...vesicles and later vesicopustules which dry up and desquamate Torres describes elongated acidophilic intranuclear inclusions in parakeratotic epithelial cells at the margin of the vesicles These are said to be surrounded by basophilic material and to be separated by clear zones from the nuclear membrane The recent observation of similar inclusions in tissue cultures of measles virus confirms Torres' observation In late stages of development of the exanthem the corium is edematous and infiltrated with monocytes containing keratohyalin granules By 72 hours the epidermal lesions have disappeared, but perivascular cuffs remain

In cases of encephalomyelitis the central nervous system shows, in the gross, congestion and petechial hemorrhages Microscopically, early cases show perivascular hemorrhage and lymphocytic infiltration, areas of demyelination later appear in brain and cord These areas are infiltrated with leukocytes and monocytes Finally, a gliosis appears

Cases of viral bronchopne...
acte
maci
lar ... appear in the
bronchial epithelium (Denton, 1925) In some cases the epithelial cells may be fused into large sheets which come to lie free in the bronchi The cell boundaries are lost, and each mass contains many nuclei which are pyknotic in the later stages On the denuded walls the epithelium rapidly regenerates, and squamous metaplasia may be seen Similar cell sheets have been described in the intestine

EXPERIMENTAL INFECTION; HOST RANGE

Josias, 1898, first indicated transmission of measles to monkeys, and successful transmission to *Macaca mulatta* (*Macacus rhesus*) was established by Anderson and Goldberger (1911) in the first unequivocal infection of any animal but man Besides *M mulatta*, *M. cynomolga*, *M sinica*, and *M fuscata* have been shown to be susceptible Monkeys can be infected ...

...man blood or catarrhal secretions (or the same from successfully infected monkeys) are used Infection can also be produced by inhalation and by contact Anderson and Goldberger (1911) found the latter very difficult to reproduce, but other considerations suggest that it may be easy when conditions are suitable Thus epidemics of measles have been seen in monkeys (Lapin, Director of the Med Biol Stat Acad Med Science Sukhund U S S R quoted by R E Shope in Account of observations by U S Med Miss to U S S R, 1955) Moreover, older monkeys kept in the laboratory have been known for years to be less susceptible to experimental infection with measles than are young and recently introduced animals Enders (1954) has been able to show that such lesser susceptibility in longer-held animals is associated ...

... varies with the dose of virus and route of inoculation used and may range from 3 to 22 days Viremia is established by the 4th or 5th day and lasts up to 15 days (Enders and Peebles, 1954) Various symptoms occur and differ in different animals The disease is rarely severe Exanthem is the most common sign Exanthem may be found in about 40 per cent of animals, conjunctivitis and catarrh, in 35 per cent, fever, in 30 per cent Mild symptoms suggestive of involvement of the nervous system have been observed occasionally Neutrophilopenia occurs in about 90 per cent of animals In severe infection all the above symptoms may occur, but usually only 2 or 3 appear in the same animal The disease may occur without any exanthem having been observed Virus can be

The prodromal symptoms are mostly catarrhal. *Onset may be sudden, with a chill followed* by sneezing, running nose, redness of the eyes, cough and fever A faint and scattered skin rash may occur, but the characteristic lesions of this early period are the Koplik or buccal spots which occur in 90 to 95 per cent of all cases These are usually bilateral and are grouped around the papilla of the parotid duct and on the mucous membrane of the lower lip. They measure from 1 to 3 mm. in diameter and are pale bluish-white in color set on a bright scarlet base They may be seen best by daylight. Similar lesions may occur in the conjunctivae and in the gastrointestinal tract, particularly in the colon

There is no interval between the prodromal stage and the fully developed disease Fever and cough become steadily worse for from 3 to 5 days, and then the rash appears, first on the forehead and behind the ears During the next 24 to 48 hours it spreads over face, neck, trunk and limbs. The fever falls after the rash is fully developed and is beginning to fade The exanthem is macular or maculopapular and may become confluent Hemorrhagic forms may occur, and when they do, the disease is severe Such hemorrhagic forms frequently show thrombocytopenia (Hudson et al, 1956) Formerly such severe cases were described as predominating in certain epidemics The rash disappears on pressure. After it fades it leaves a brownish staining which is followed by branny desquamation There may be frank conjunctivitis with photophobia Leukopenia is usual at the height of the infection.

Virus is present in the blood and in the nasopharyngeal secretions, probably during the whole prodromal period and up to 30 hours following the appearance of the rash

Bacterial complications such as otitis media, with perforation of the drum, and bronchopneumonia are not infrequent, but with modern chemotherapy are rarely serious The pneumonia may be purely bacterial and due to streptococci, pneumococci or *H. influenzae.* It was in such cases formerly that the high mortality occurred. A pure viral type of pneumonia has also been described (Moore and McCordock, 1934; Corbett, 1945; Milles, 1945). In the roentgenogram the picture resembles primary atypical pneumonia; sometimes in addition miliary nodules are observed

Encephalomyelitis is the most serious complication today. Fortunately, it is rare (about 1 in 10,000 cases), but in certain epidemics the incidence may be higher It shows a definite tendency to be associated with the more severe cases of the disease, is more frequent in girls than in boys and in the white race than in the colored It may develop before the disappearance of the exanthem and the usual period of fever, but usually there have been several days of return to normal when, abruptly, the temperature begins to rise again, and the patient becomes drowsy or hyperexcitable with convulsions Headache, vomiting and coma occur Protein and cells are increased in the spinal fluid The mortality is from 10 to 16 per cent but rises to 38 per cent in those patients who show coma. A proportion of those who survive show permanent mental and physical changes The incidence of such sequelae is stated differently by various observers: from 15 per cent by Hodes (personal communication) to 65 per cent by Ford, 1928 Besides encephalomyelitis other forms of involvement of the central nervous system occur but more rarely. These are myelitis, radiculitis or neuroretinitis.

It has been pointed out above that lesions comparable with Koplik spots may occur in the gastro-intestinal tract The appendix may be involved, and either these lesions or the hyperplasia of the lymphoid tissue can lead to symptoms of appendicitis Appendectomies because of faulty diagnosis are not unknown

Goldfield et al (1955) have described changes in the electrocardiograms of 19 per cent of patients with measles The changes were transient but could not be attributed to occurrence of fever, complications or disturbances of acid-base balance

PATHOLOGIC PICTURE

The catarrhal inflammation is not typical ... the body may be

pendix. The cells (often called Warthin-Finkeldey cells from their presumed original observers) measure up to 100 μ across and may contain as many as 100 nuclei Actually,

disease in cynomolgus monkeys Viremia could be demonstrated 4 to 5 days after intravenous or intranasal inoculation and persists for 2 to 5 days (Enders et al, 1957) The disease picture has been described above. Complement-fixing antibodies appear on about the 14th day, diminish in titer after several weeks, but are still detectable at least 8 months after inoculation As indicated above, it appears that monkeys become spontaneously infected with measles in the laboratory, and isolation of apparently typical measles virus from monkey kidneys has been described by Ruckle (1956) by Frankel et al (1957), and by Muething et al (1957) Using a strain of measles virus which had been modified by continued passage in human amnion tissue culture and in which the refractile stellate cell had become predominant (see above), Enders et al (1957) were able to obtain successful transmission in the chick embryo by the amniotic sac By passing at 9-day intervals, the strain was maintained in the chick embryo for 7 passages The chick virus was neutralized by convalescent phase human and monkey sera Attempts to transmit strains of earlier tissue culture passage to the chick embryo were not successful Katz et al (1958) have also been able to grow a strain of measles virus already well established in the laboratory in cultures of chick amniotic membrane For the first 4 passages no cytopathic changes were produced, but thereafter they occurred regularly

Adams and Imagawa (1957) have drawn attention to a most interesting antigenic relationship between the virus of measles and that of canine distemper Thus the characteristic cytopathic changes of measles virus in tissue culture can be neutralized by specific distemper antiserum, ferrets immunized with measles virus show modified disease when challenged with virulent measles virus, and distemper in the suckling mouse can be neutralized with convalescent human antimeasles serum or serum from ferrets immunized with measles virus These interesting observations merit much further attention It is particularly striking to be presented with such evidence of serologic relationship for these two viruses whose similar biologic behavior in their respective hosts has been apparent to students of measles or distemper for years

DIAGNOSIS

During an epidemic diagnosis is easy The enanthem (Koplik's spots) rather than the rash is diagnostic of sporadic cases Tompkins and Macaulay (1955) have been able to demonstrate the Alagna (Warthin-Finkeldey) multinucleate giant cells in the sputum and the nasal mucus during the prodromal stage and up to the appearance of the exanthem This may well prove to be a simple and useful diagnostic procedure In 5 per cent of cases Koplik s spots may not be observed, and differentiation of mild cases from rubella may be difficult In rubella early and marked adenitis is characteristic Severe forms of catarrhal laryngitis preceding the measles rash must be distinguished from that of scarlet fever, rubella and smallpox The rash of infectious mononucleosis or that of dengue may be morbilliform, as may allergic rashes due to drugs The Debre test may also be used in diagnosis In this test intradermal injection of measles convalescent serum will prevent appearance of measles rash specifically in the area infiltrated

TREATMENT

In uncomplicated cases treatment is largely symptomatic Bed rest and light diet are indicated along with subdued light because of the conjunctivitis and photophobia A sedative or antitussive may be required for the cough Secondary bacterial infections can be combated successfully with sulfonamides or antibiotics The use of these drugs prophylactically is open to question Weinstein (1955) presents data indicating that secondary bacterial complications, especially with *H influenzae*, occur twice as often when antibiotics have been used in attempted prophylaxis Therefore, chemotherapy should not be employed until there is definite evidence of bacterial complication

Specific therapy consists of the use of serum antibodies prepared from convalescent serum, pooled adult serum or placental extracts. The use of any of these depends on the fact that most adults have had measles and therefore collection of adult blood will contain large amounts of specific antimeasles gamma globulin More recently, concentrates of fractionated gamma globulin, containing mostly

demonstrated in the buccal mucosa and secretions and in the blood of infected monkeys The pathologic picture of the enanthem and the exanthem in monkeys is essentially similar to that in man. No mammals other than primates have been successfully infected with measles

ETIOLOGY

The virus in blood or nasopharyngeal secretions passes through Berkefeld N or Seitz EK filters It can be preserved at −72° C or −35° C. for periods up to 4 weeks and for several days at 0° C At room temperature infectivity is retained for 1½ days It may be dried in vacuo from the frozen state and then will remain active for at least 15 weeks At −72° C. it resists a pH of 6 for 60 hours, but lower pH ranges rapidly inactivate it It withstands 10 per cent ether for 40 minutes at room temperature

Many claims of successful cultivation of the virus of measles have been made and are reviewed by Rake et al. (1941) on studies with tissue culture, and by Shaffer et al (1941) on studies with chicken embryos In many cases the agents cultivated would seem not to be those responsible for measles The first successful cultivation of measles seems to have been that of Plotz in chick embryo tissue in 1938, and Rake and Shaffer in 1939 demonstrated transmission of measles to monkeys with virus grown in chicken embryos after inoculation on the chorio-allantois by the Burnet technic, or into the amniotic or the allantoic cavities This work was complicated by the fact that no alteration was observed in the tissues, either in the gross or microscopically Such egg-passaged virus also was capable of producing disease in man which was but slightly modified in early passages but became more modified with subsequent passage

In 1954 Enders and Peebles described the cultivation, in human postnasal tissue growing in roller tubes, of a filterable agent from the blood and throat washings taken within the first 24 hours from a patient with measles Cytologic changes appeared in from 4 to 10 days. Subsequently, a similar agent was grown in human or rhesus renal cells again from blood or throat washings, or in 1 case from lung Similar viruses have been obtained by Cohen et al. (1955) and by Frankel et al (1957). The latter also isolated the virus from conjunctiva and from stools 4 to 5 days after appearance of the rash and reported successful primary isolation in both monkey kidney cells and in human amnion. Enders et al (1957) have described in detail the changes appearing in the tissue cells In human renal cells multinucleated giant cells appear These cells show intranuclear acidophilic inclusion bodies and masses of eosinophilic material in the cytoplasm Similar giant cells have been observed in human amnion, in various lines of human malignant epithelial cells and in cultures of human fibroblasts No cytopathogenic effect has been seen in bovine or chick tissues tested After continued passage the cytopathic effects change and, besides the giant cells, increasing numbers of refractile stellate cells appear. In time these latter cells may be the only ones observed They also show intranuclear inclusions Studies of distribution of measles viral antigen within the cells have been made by Cohen et al. (1955) and by Baker et al (1957) using the fluorescent antibody technic of Coons and Kaplan Fluorescence was seen by Cohen et al by the 5th day in the cytoplasm and later as masses in the nucleus It increased in amount with tissue culture passage Baker et al found fluorescent antigen combination as early as the 4th day Fluorescence could be induced only with measles convalescent serum. The technic was more sensitive than the complement-fixation test in detecting antimeasles antibody. Enders et al. (1957) describe the development of both neutralization tests—testing the capacity of sera to prevent the cytopathogenic effects of the virus—and complement fixation, using supernatant fluid from tissue cultures of infected human renal or amnion cells as antigen By both technics it can be shown that acute phase sera show no antibodies but that an increase appears soon after the rash appears and reaches titers as high as 1:512. These high initial titers are maintained for up to 4 months (longest tested) but presumably will decrease after that time, since sera from patients with past history of measles show, in average, lower titers.

Tissue-culture measles virus produces mild

disease in cynomolgus monkeys Viremia could be demonstrated 4 to 5 days after intravenous or intranasal inoculation and persists for 2 to 5 days (Enders et al, 1957). The disease picture has been described above. Complement-fixing antibodies appear on about the 14th day, diminish in titer after several weeks, but are still detectable at least 8 months after inoculation As indicated above, it appears that monkeys become spontaneously infected with measles in the laboratory, and isolation of apparently typical measles virus from monkey kidneys has been described by Ruckle (1956), by Frankel et al (1957), and by Muething et al (1957). Using a strain of measles virus [illegible] had become predominant (see above), Enders et al (1957) were able to obtain successful transmission in the chick embryo by the amniotic sac By passing at 9-day intervals, the strain was maintained in the chick embryo for 7 passages The chick virus was neutralized by convalescent phase human and monkey sera Attempts to transmit strains of earlier tissue culture passage to the chick embryo were not successful Katz et al (1958) have also been able to grow a strain of measles virus, already well established in the laboratory in cultures of chick amniotic membrane For the first 4 passages no cytopathic changes were produced, but thereafter they occurred regularly

gamma but also some beta globulin, have been used. Before the availability of the globulin concentrates therapy was administered, almost entirely, during the incubation period when exposure was known to have occurred, to prevent or modify the disease Complete suppression is advisable in the case of very young or sick children and is obtained by use of a large dose of whatever preparation is employed, sufficiently early after exposure In children 3 years or younger this would amount to 5 cc of convalescent or 10 cc. of adult serum within 6 days after exposure. For older children, the age is multiplied by 2 for convalescent serum or by 4 for adult serum to obtain the dose in cubic centimeters For attenuation a smaller dose is used, or the injection is given later after exposure Thus the same doses may be used as for prevention but given later than 6 days after known exposure, or half the amount may be given on about the third day. In the case of globulin concentrates, 0 5 cc. given to children under 6 years within 7 days of exposure results in complete protection of about half, and modified disease in the others If with any of the preparations an ideal dose is achieved, the disease may be modified to a point where no true malaise occurs and yet the individual is protected against any subsequent exposure. Stillerman et al. (1944) have pointed out the frequency with which very mild symptoms are seen by the careful observer following doses presumed to be preventive Without careful examination such symptoms are usually entirely overlooked However, if too large a dose is used, resulting in no symptoms or markedly modified ones, the protection produced will be at best only temporary The failure of markedly modified experimental disease to produce immunity has also been observed.

Although the above treatments are often

highly concentrated preparations of immune globulin, showing antibody titers 15 to 35 times as high as the original plasma pool, attempts have been made to influence the course of the disease with injections given as late as the prodromal stage or even later Stokes et al (1944) believe that the incidence of encephalitis can be affected, but Greenberg et al. (1955b) could obtain no such evidence, although encephalitis was apparently less frequent in individuals in whom early modifying doses of gamma globulin had been given (Greenberg et al. 1955a) Apart from encephalitis the prognosis of the disease is good today.

EPIDEMIOLOGY

Measles is one of the most infective of the exanthemata It is particularly infective during the catarrhal prodromal stage when the

with secretions can carry the disease for a short period, as can on rare occasions indi-

patients

wanes

isles is

endemic in all populous regions and occurs in epidemic form at approximately 3-year intervals. Only 1 per cent of susceptible individuals fails to contract the disease on their first close contact with a case in the infective stage By the age of 20 some 90 per cent of persons in civilized countries have had the

attacks are unusual but may occur, and certain rare individuals appear never to acquire an immunity and suffer repeated typical attacks of the disease

CONTROL MEASURES

Early reporting of cases of measles is important. When the disease is recognized in a community any known susceptible child with catarrhal symptoms is suspect, particularly if there is history of exposure, and the appearance of enanthem should be watched for. Isolation of the patient and disinfection of articles soiled with catarrhal secretions should be carried out from the first appearance of the prodromal symptoms until 4 to 5 days after appearance of the rash—a period of some 9 to 10 days in all Quarantine of children during epidemics in large communities is of little value. Quarantine of exposed individuals for 14 days in sparsely settled communities may be practiced, at least to the extent of forbidding such individuals to attend school or public gatherings Segregation of infants,

and encephalitis, are more frequent in adults than in children. When encephalitis occurs it usually appears 3 or 4 days after the appearance of the rash (Mitchell and Pampiglione, 1954). Headache and apathy may be followed rapidly by coma. The incidence of encephalitis after rubella is definitely less than after measles. The mortality is 20 per cent (Miller, 1956), but if death does not occur, despite evidence of widespread involvement of the central nervous system, complete though slow recovery is the rule. Gross mental disturbance may occur.

Gregg (1941) first showed the serious effects on the fetus of rubella occurring in the mother in the early months of pregnancy. Attention was drawn to cataract and cardiac malformations. Subsequent studies in Australia and later in the United States, Britain and Europe have confirmed the original observations and have shown that the effects on the fetus are not due to any particularly severe strain of the virus. Attention should be drawn to 3 surveys in Australia of the results of rubella during pregnancy (Gregg et al., 1945, Swan et al., 1946, Swan 1949). From these it appears that rubella produces serious congenital malformations only when it occurs during the first 4 months of pregnancy. The rate may vary from 83 per cent if infection of the mother occurs during the first postconceptual month to 61 per cent in the 4th month. American statistics (Ingalls and Gordon, 1947, Ober et al. 1947) suggest a lower defect rate—50 per cent following rubella in the first trimester. However, it should be pointed out that the American statistics were collected at an earlier date after birth than were the Australian, and many of the commoner abnormalities, particularly deafness, would not be included. Although of less frequency than the abnormalities in the [illegible]

that the most frequent defect is deafness with secondary mutism (75 per cent). *Microcephaly occurs in 70 per cent; eye defects,* particularly cataract, in 66 per cent, and cardiac malformations in 63 per cent. Dental abnormalities, often of major character, appeared in 45 per cent. In a more recent communication Greenberg et al. (1957) suggest that actually the incidence of defects may be considerably lower than indicated by all other surveys, i.e., not higher than 12 per cent. These workers believe that other surveys suffer by being "retrospective" rather than "prospective." However, it should be pointed out that since the data in this study were obtained during the first year after birth, defects in dentition and some deficiencies in hearing would not have been detected.

PATHOLOGIC PICTURE

Although the lymph nodes are swollen, and some authors note enlargement of the spleen, [illegible]

A small increase in protein and a large increase in number of lymphocytes occur in the spinal fluid. [illegible]

patent ductus arteriosus and foramen ovale. Swan (1944) notes that no sign of endarteritis obliterans could be found in the ducti arteriosi. The children were usually undernourished, with indications that all cells were involved to some degree. Affected eyes were small (microphthalmia), and the lens showed massive central or nuclear necrosis with distortion of the peripheral lens fibers. Carruthers, 1945, examined the ears in one case with deafness and found absence of differentiation of primitive cells to form the organ of *Corti*.

EXPERIMENTAL INFECTION, HOST RANGE

The disease may be transmitted to susceptible children by the inoculation of material containing active virus. Virus may be found in the blood in the natural disease and also in the nasopharyngeal secretions from the time of the appearance of the prodromal symptoms up to 30 hours after the appearance of rash. As Hiro and Tasaka, 1938, showed in their original observation, not all children showed typical infection, and some

Rubella

(SYNONYMS German Measles, rubeola,* epidemic roseola, 3-day measles, *Rotheln* or *Roteln, rubéole*)

INTRODUCTION

Rubella is one of the frequent mild exanthemata, usually occurring in childhood It is now recognized that the disease may produce serious effects in the fetus when it is acquired by the mother at certain stages of pregnancy, but in the mother herself, the disease, if somewhat severer than occurs in childhood, is not serious. Apart from effects in the unborn child, the prognosis is usually excellent

HISTORY

Although rubella undoubtedly has existed for many centuries, confusion of it with other exanthemata has obscured its true identity until comparatively recently. Wagner, 1829, first separated it from measles and scarlet fever, but his observation was largely ignored for the next 50 years Confusion between rubella and measles still exists, and probably

on the oral mucosa in measles but not in rubella. Until comparatively recently rubella has been considered a mild and unimportant disease, but this view has been altered by the observation of Gregg (1941) and others, on the serious effect of the disease in pregnant females on the fetus in utero Recently (1954), Anderson has demonstrated the cultivation of the agent in tissue culture

CLINICAL PICTURE

The symptoms are usually mild, particularly in children The incubation period is usually 18 days, with a range from 14 to 23 The disease begins with a short prodromal peroid of mild catarrhal symptoms, fever and malaise but with no Koplik's spots When the rash appears it starts on the head and the face and spreads within 24 hours to the neck and the trunk In the early stages it resembles the rash of measles, since it consists of round, pink and slightly raised macules, usually discrete. If confluent, it resembles the rash of scarlet fever; rarely, it may be papular. The exanthem lasts only 2 or 3 days and characteristically may appear on new areas after it has faded from those first affected. Slight branny desquamation may occur Although Koplik's spots do not occur, a fine red enanthem may appear on the soft palate, and the tonsils may be enlarged. Fever is usually slight and continues while the rash persists Lymphadenitis is characteristic and affects particularly the cervical and the occipital nodes, which may be tender. The swelling may persist for 2 or 3 weeks. Complications are rare, and those that occur, such as arthritis, neuritis

* Rubeola, unfortunately, has been used as a synonym for both measles and rubella

characteristic. A rubellalike rash may be produced by allergy to drugs.

TREATMENT

The treatment of the disease is usually symptomatic, and in many cases the disease is so mild that not even rest in bed is required. The demonstration of the frequent and serious effects produced in the fetus by rubella acquired by the mother during the first 4 months of pregnancy have changed ideas as to the gravity with which this infection should be viewed If a pregnant woman is exposed to rubella, prevention of the infection may be attempted by the use of immune globulin in one form or another (Chap 34). However, the value of such prophylaxis is debatable, and certainly the results are not consistent Barenberg et al (1942) present indication of some suppressive action, and McLorinan (1950) showed that 4 ml. of gamma globulin from patients convalescent from rubella will prevent disease in the majority of susceptible individuals if given not later than the 8th day after contact More recently, Korns (1952) has shown that certain lots of serum globulin are effective It is possible that the use of serum or gamma globulin to protect the mother during pregnancy may also prevent malformations in the fetus

Because unfortunately the effect of convalescent serum or globulin is not entirely certain, the problem remains as to how to handle the case of a woman exposed to and later developing rubella during the first 3 or 4 months of pregnancy Many factors have to be taken into consideration, including parity and religion When rubella develops early in pregnancy in a recently married, healthy young woman, the situation should be explained in detail to the couple, and therapeutic abortion advised In the case of an older childless couple, the pregnancy should be allowed to go to term, and a calculated risk taken of the consequences of rubella to the fetus

EPIDEMIOLOGY

Rubella occurs in epidemics most frequently in the winter and spring months Incubation is from 14 to 21 days—usually 18 An attack is almost always followed by permanent immunity Diagnosis of second attacks of rubella are usually due to confusion with other mild exanthemata, as has been discussed elsewhere. The disease is transmitted primarily by virus-laden discharges from the nasopharynx of the patient in the prodromal period, or during the first 24 hours after appearance of rash Transmission usually occurs directly but may also occur by means of articles freshly soiled with infected secretions. The contagiousness is less than in measles, as is indicated by the higher attack rate for rubella in adults

CONTROL MEASURES

Before the serious results of an attack of rubella early in pregnancy were recognized, control measures were deemed of little importance It is now clear that every attempt should be made to assure that girls contract rubella before the child-bearing age If a pregnant woman has not had rubella, or even if she has (because of possible faulty diagnosis of the earlier attack), every attempt should be made to isolate her from cases of the disease during the first 4 months of pregnancy. If, despite precautions, she is exposed, especially if she is older and thus far childless, prophylaxis with immune globulin should be attempted for lack of anything better A definitive study of conditions under which such globulin may be effective is urgently required

may have the disease without any sign of rash Anderson (1949) was able to infect volunteers with a spray of freshly prepared throat washings taken from patients with rubella during the first 24 hours after appearance of rash. In these cases the incubation period varied from 13 to 20 days, and lymphadenopathy might precede the rash by as long as 6 days. Rubella could be transmitted naturally to susceptible contacts exposed to these children during their actual disease. Some volunteers apparently had subclinical infections. After injection of material, the incubation period varies from 5 to 7 days Krugman et al (1953) were also able to produce infection in volunteers by intramuscular or intranasal inoculation of blood or nasopharyngeal washings taken from patients 13 hours after the appearance of their rash In this case the incubation period was from 12 to 16 days, regardless of the route of inoculation Contact infection by exposure to the inoculation disease occurred, and some of the inoculated volunteers showed what was apparently *rubella sine eruptione*.

Hess, 1914, was the first to demonstrate possible successful transmission of rubella to monkeys. He used *M. mulatta* and inoculated them with blood taken from patients within 24 hours of the appearance of the rash One animal showed a sharp febrile response in the 19th day. Habel (1942) also used *M mulatta* (rhesus monkeys). Blood or nasopharyngeal washings, collected within 12 hours of appearance of rash, were used In 13 out of 16 attempts mild disease was produced following subcutaneous, intraperitoneal, intranasal or intravenous inoculation of filtered or unfiltered material. Incubation was from 7 to 9 days Pyrexia was slight, as was leukopenia. The exanthem, which was not always present, consisted of sparse pink macules, chiefly on the trunk. The disease was passed from monkey to monkey for 5 passages The disease did not in every case protect against challenge inoculation 1 to 3 months later Krugman et al. (1953) were unable to infect cynomolgus monkeys

ETIOLOGY

The successful transfer of rubella to children accomplished by Hiro and Tasaka, 1938, and discussed above, was with nasal washings filtered through Berkefeld W or Seitz EK filters. Habel (1942) was able to obtain successful transmission after passage through Berkefeld N filters, and Anderson (1949) obtained passage of the agent through a filter with pore diameters of 800 μ. The virus remains viable after 3 months at $-70°$ C. or after 9 months storage in a dry-ice chest

Habel (1942) described the passage of rubella on the chorio-allantois of the chicken embryo No lesions developed, but successful transmission to the monkey was noted after 5 such passages. This work has not yet been confirmed

Anderson (1954) was able to cultivate an agent in monkey kidney cells in roller tubes from cases of rubella After 5 passages there appeared on the 5th day, groups of multinucleated cells. The cytopathogenic agent could be passed subsequently to human fetal lung and other fetal tissues. The cytopathogenic changes were neutralized by rubella convalescent serum but not by measles convalescent serum.

DIAGNOSIS

Rubella must be distinguished from measles, exanthem subitum, erythema infectiosum, infectious mononucleosis, and from dengue in those areas where the latter disease occurs. Differential diagnosis from the first is best established by the absence of Koplik spots, but the milder course of rubella, the enlarged cervical nodes and the distribution of the exanthem are useful features Exanthem subitum starts abruptly with fever, and rash is unusual before the fever terminates; the disease is even milder than rubella and rarely occurs in other than infants and young children. In erythema infectiosum the rash is characteristic, and the patient rarely shows any other sign or symptom—not even fever or malaise The rash in infectious mononucleosis is inconstantly present and protean in type. It may mimic any of the common exanthemata. Usually, however, there is a marked rise in the count of primitve monocytes and lymphocytes. Heterophile antibodies are found In dengue, the abrupt and high fever and the severe pain in muscles and joints are

characteristic. A rubellalike rash may be produced by allergy to drugs.

TREATMENT

The treatment of the disease is usually symptomatic, and in many cases the disease is so mild that not even rest in bed is required The demonstration of the frequent and serious effects produced in the fetus by rubella acquired by the mother during the first 4 months of pregnancy have changed ideas as to the gravity with which this infection should be viewed. If a pregnant woman is exposed to rubella, prevention of the infection may be attempted by the use of immune globulin in one form or another (Chap 34) However, the value of such prophylaxis is debatable, and certainly the results are not consistent Barenberg et al (1942) present indication of some suppressive action, and McLorinan (1950) showed that 4 ml. of gamma globulin from patients convalescent from rubella will prevent disease in the majority of susceptible individuals if given not later than the 8th day after contact More recently, Korns (1952) has shown that certain lots of serum globulin are effective. It is possible that the use of serum or gamma globulin to protect the mother during pregnancy may also prevent malformations in the fetus

Because unfortunately the effect of convalescent serum or globulin is not entirely certain, the problem remains as to how to handle the case of a woman exposed to and later developing rubella during the first 3 or 4 months of pregnancy Many factors have to be taken into consideration, including parity and religion When rubella develops early in pregnancy in a recently married, healthy young woman, the situation should be explained in detail to the couple, and therapeutic abortion advised In the case of an older childless couple, the pregnancy should be allowed to go to term, and a calculated risk taken of the consequences of rubella to the fetus

Exanthem Subitum and Erythema Infectiosum

(**Exanthem subitum,** SYNONYMS: Roseola subitum, roseola infantilis, roseola infantum, pseudorubella, exanthem criticum, sixth disease, rose rash of infants, Zahorsky's disease **Erythema infectiosum,** SYNONYMS Duke's disease, fourth disease, fifth disease, parascarlatina, *ringel rötheln, örtliche rötheln*, megalerythema epidermicum, grossflecken, *exantheme variable*, erythema simplex marginatum, erythema infantum febrile, *epidemische kindervotlauf*)

EXANTHEM SUBITUM

INTRODUCTION

Exanthem subitum is a mild but acute illness with sudden onset, occurring for the most part in infants and young children It is mildly contagious, and epidemics have been described particularly in orphan homes or maternity hospitals Characteristically, there is fever and malaise of 3 to 5 days duration, which tends to terminate abruptly on appearance of the exanthem The prognosis is excellent

HISTORY

The disease probably has been known for over a century, but its existence was obscured by the many other mild exanthems with which it was confused (see below). It was characterized as a separate disease entity by Zahorsky (1910) in the United States This report was followed immediately by reports from many parts of the world.

CLINICAL PICTURE

Although most cases occur in the first few months or 2 years of life, cases are not rare up to 4 years, and 1 case has been described in a 31-year-old woman Both sexes are equally affected. The onset is usually sudden with rise in temperature to 105° or 106° F, this abrupt onset may be preceded by a mild inflammation of the nose, the throat and the middle ear and by a cough (McQuitty, 1955) The high fever may induce convulsions. Fever lasts up to 5 days, is of intermittent or remittent type and usually disappears abruptly, together with other symptoms, on appearance of the typical rash Other common symptoms are malaise, irritability and diarrhea Mild meningismus is seen occasionally during the height of the fever. Clemens (1945) has described an enanthem on the soft palate which McQuitty (1955) says occurs during the febrile period The exanthem, which appears only rarely before the disappearance of fever, is typically finely macular but may be maculopapular Where thickest, on thighs and buttocks, it tends to be surrounded by a pale halo It appears first on the trunk, later on neck and arms. Rash is rare and sparse on

the face. The exanthem fades rapidly without desquamation or pigmentation. Cases without rash but with high fever (roseola sine eruptione) occur and cause difficulties in diagnosis. The disease may recur after apparent recovery Leukopenia with absolute lymphocytosis is found particularly in the middle of the febrile period Such lymphocytosis may be accompanied by slight enlargement of the lymph nodes Monocytes may be increased

Etiology

The causative agent is not definitely known Attempts to demonstrate a bacteriologic etiology have not been successful. Kempe et al (1950) have transmitted the disease from one infant to another by intravenous injection of bacteria-free serum collected on the third but not the first day of fever After an incubation period of 9 days, typical exanthem subitum occurred The same authors apparently transmitted the disease to monkeys from both donor and recipient children by means of serum or throat washings taken on the third day of fever. Incubation in the monkey was 4 to 5 days A febrile response was induced in other monkeys by serum taken on the second day of fever and inoculated either untreated or after Seitz (EK) filtration. After the febrile episode the monkeys were refractory for at least 9 days Neva and Enders (1954b) isolated a virus cytopathic for both epithelial and fibroblastic human cells from a case clinically resembling exanthem subitum. Antibodies to the virus appeared in the convalescent serum of the patient Other studies indicate that the agent belongs to the adenovirus group

Diagnosis

Exanthem subitum must be distinguished from measles, rubella, scarlet fever, infectious mononucleosis and dengue among the well-characterized diseases but also from a large number of ill-defined exanthematous conditions (see below). From measles it may be distinguished by mildness, absence of Koplik spots and distribution of rash. The abrupt termination of fever before appearance of rash distinguishes it from all the characterized diseases listed above From rubella it is also distinguished by its abrupt onset. Scarlet fever presents a severe angina, a different hematologic picture and a type of rash entirely different, especially as regards the typical residual staining and marked desquamation. Dengue differs in its secondary rise of temperature and intense pains in bones, joints and muscles Infectious mononucleosis presents an entirely different blood picture and is characterized by the appearance of heterophile antibodies The rash of exanthem subitum must also be distinguished from that produced by sulfonamides and certain other drugs

Treatment

The treatment is entirely symptomatic, and the prognosis is excellent.

Epidemiology

The disease tends to occur in spring and fall. The incubation period is about 10 days with a range of from 7 to 17 The disease can assume epidemic form, and as many as 30 per cent of contacts in the infant age group may show overt disease Nevertheless, it does not usually spread in families, and many general practitioners are apt to regard it as noncontagious. In view of the occurrence of the disease without rash, and the frequent transient nature of the rash when it does occur, it appears to the author that the low contagiousness is actually only apparent and results from a high proportion of subclinical or unrecognized infections.

ERYTHEMA INFECTIOSUM

Introduction

Besides the exanthematous diseases discussed in this and the preceding two chapters—measles, rubella and exanthem subitum—there are many others of similar clinical nature seen by the pediatrician, which from their characteristics are in all probability of viral origin In practice the numerous attacks of mild exanthemata seen in childhood are labeled atypical and second (or third) attacks of one of these 3 well-recognized diseases, particularly rubella. The evidence for such second attacks is scanty, and indeed their occurrence is inherently improbable It is

clear that we are now in an era when many of the diseases in this indeterminate group will be characterized and their etiology established Already at least one has been shown to be due to an ECHO virus, and Neva and Enders (1954a) have described a cytopathic virus, which may be cultivated in human fibroblasts and was isolated from an epidemic of a mild rubellalike exanthem appearing near Boston in 1951 The cytologic changes were neutralized by convalescent sera of patients. Subsequently, similar epidemics—with in some cases isolation of the same virus—have been seen in Pittsburgh and elsewhere

One disease of this group which presents a characteristic clinical picture, which when looked for is found surprisingly frequently and from which a virus has recently been isolated on more than one occasion, is erythema infectiosum This virus will be discussed briefly here.

The disease is mildly contagious with at most only insignificant malaise or febrile response and indeed frequently with no other symptom or sign besides the characteristic rash

History

The disease was first described in Austria by Escherich in 1886, and shortly thereafter many other epidemics were recognized in Central Europe. Subsequently, the disease has been described in typical form in most countries of the world

Clinical Picture

The disease occurs characteristically in children of from 4 to 12 years of age, but occasional cases are seen in infants and also in adults in whom the symptoms may be slightly more severe Typically, the disease begins with the appearance of rash, since subjective symptoms are very slight and often are absent Rash first appears on the cheeks, which become fiery red and appear windblown They may be burning and even painful The margin of the red area is sharply delimited and raised, resembling erysipelas Within the cheek lesion isolated papules and vesicles may appear and later become crusted There is circumoral pallor Later, rash appears on the limbs and to a lesser degree on the trunk This rash starts as discrete macules which increase rapidly in size and then fuse At the same time the central area fades, leaving a typical lacework pattern of geographic outlines The rash is characteristically evanescent, but even months after its initial disappearance it can be reactivated by heat, friction or other means Itching is an occasional complaint There is no staining or desquamation Complicating herpes simplex is seen occasionally. There may be slight malaise, sore throat, weakness and low-grade fever in an occasional child Since relapse is characteristic, the disease may last several weeks or even months without, however, producing any real inconvenience The blood picture is normal; lymph nodes are not enlarged In exceptional cases a definite prodromal state with fever, coryza, malaise and nausea and diarrhea has been described

Etiology

The clinical characters and the epidemiology of the disease suggest a viral etiology However, until 1955 no etiologic agent had been isolated In the spring of 1957, Werner et al. studied an epidemic in a school in Pennsylvania A cytopathic agent was isolated in 3 instances from stools and throat washings by repeated passage in monkey kidney cells The changes in the growing cells were characteristic with the appearance of giant multinucleated cells containing intranuclear acidophilic inclusions Complement-fixation tests carried out with the tissue culture agent showed an increase in titer of convalescent over acute-phase sera Subsequently, the new viral agent has been grown and produced cytopathic changes in human amniotic cells In 1956, Henle accomplished the isolation in monkey kidney cells of 2 strains of a similar agent from throat swabs of cases of erythema infectiosum then occurring in another town in southeast Pennsylvania (personal communication)

Diagnosis

This exanthem has to be differentiated from the pool of uncharacterized exanthemata discussed above and also from scarlet fever, rubella, measles and exanthem subitum. However, when it occurs in epidemic form such differentiation is easy The exanthem is typi-

the face The exanthem fades rapidly without desquamation or pigmentation. Cases without rash but with high fever (roseola sine eruptione) occur and cause difficulties in diagnosis The disease may recur after apparent recovery Leukopenia with absolute lymphocytosis is found particularly in the middle of the febrile period Such lymphocytosis may be accompanied by slight enlargement of the lymph nodes Monocytes may be increased

Etiology

The causative agent is not definitely known Attempts to demonstrate a bacteriologic etiology have not been successful. Kempe et al (1950) have transmitted the disease from one infant to another by intravenous injection of bacteria-free serum collected on the third but not the first day of fever After an incubation period of 9 days, typical exanthem subitum occurred The same authors apparently transmitted the disease to monkeys from both donor and recipient children by means of serum or throat washings taken on the third day of fever Incubation in the monkey was 4 to 5 days A febrile response was induced in other monkeys by serum taken on the second day of fever and inoculated either untreated or after Seitz (EK) filtration After the febrile episode the monkeys were refractory for at least 9 days Neva and Enders (1954b) isolated a virus cytopathic for both epithelial and fibroblastic human cells from a case clinically resembling exanthem subitum. Antibodies to the virus appeared in the convalescent serum of the patient. Other studies indicate that the agent belongs to the adenovirus group.

Diagnosis

Exanthem subitum must be distinguished from measles, rubella, scarlet fever, infectious mononucleosis and dengue among the well-characterized diseases but also from a large number of ill-defined exanthematous conditions (see below). From measles it may be distinguished by mildness, absence of Koplik spots and distribution of rash. The abrupt termination of fever before appearance of rash distinguishes it from all the characterized diseases listed above From rubella it is also distinguished by its abrupt onset. Scarlet fever presents a severe angina, a different hematologic picture and a type of rash entirely different, especially as regards the typical residual staining and marked desquamation Dengue differs in its secondary rise of temperature and intense pains in bones, joints and muscles. Infectious mononucleosis presents an entirely different blood picture and is characterized by the appearance of heterophile antibodies The rash of exanthem subitum must also be distinguished from that produced by sulfonamides and certain other drugs

Treatment

The treatment is entirely symptomatic, and the prognosis is excellent.

Epidemiology

The disease tends to occur in spring and fall The incubation period is about 10 days with a range of from 7 to 17. The disease can assume epidemic form, and as many as 30 per cent of contacts in the infant age group may show overt disease Nevertheless, it does not usually spread in families, and many general practitioners are apt to regard it as noncontagious In view of the occurrence of the disease without rash, and the frequent transient nature of the rash when it does occur, it appears to the author that the low contagiousness is actually only apparent and results from a high proportion of subclinical or unrecognized infections.

Control Measures

The Herpes Virus Group

INTRODUCTION

A group of viruses having similar characteristics has been designated Herpesvirus (Andrewes, 1954) Three of the group members are pathogenic for man *Herpesvirus varicellae* is considered elsewhere (Chap. 39) *Herpesvirus hominis* (Virus of Herpes Simplex) and *Herpesvirus simiae* (B Virus) are considered here

Herpesvirus hominis is a common parasite of man, because of long association, a mutually satisfactory modus vivendi has been established whereby the parasite only infrequently incapacitates its host and thus assures itself of wide distribution This is in contrast with the severe infections it produces when artificially introduced into other hosts, such as the rabbit In the same way *Herpesvirus simiae* infection is usually subclinical in monkeys, but accidental infection of man leads to fatal disease

The physician is concerned with the diagnosis and the care of the small number of human beings in whom *Herpesvirus hominis* produces a protean picture of clinical disease, or in whom an accidental infection with *Herpesvirus simiae* has taken place

The common characteristics of infection by these 2 viruses in their natural hosts are (1) tissues preferentially but not exclusively attacked are those derived from the embryonic ectoderm, (2) superficial vesicles characterize the visible lesions, (3) histologically, the infected cells show intranuclear inclusions; (4) the viruses are readily isolated from infected tissues.

HERPESVIRUS HOMINIS

(SYNONYM: Virus of Herpes Simplex)

HISTORY

Lowenstein, 1919, was the first to publish evidence that a virus from human herpetic keratitis and from the vesicles of herpes labialis would produce specific lesions on the cornea of a rabbit. He credited Gruter with priority for similar unpublished experiments in 1912 and 1913. Gruter, 1920, described the successful transmission of the disease from an experimentally infected rabbit back to the normal cornea of a blind man

In 1920, it was found that herpesvirus could cause encephalitis in rabbits; Doerr, 1920; and in the same year, an active agent with the characteristics of herpesvirus was isolated from a patient who had died of von Economo's encephalitis, Levaditi and Harvier, 1920 This gave rise to the idea that herpes virus might be a less-virulent varient of the "virus of encephalitis," Levaditi, 1922. However, with increased experience it is now known that while *Herpesvirus hominis* is one of many viruses that can cause human encephalitis, it is not the cause of an epidemic variety

Andrewes and Charmichael (1930) observed that a large proportion of normal adults had in their blood neutralizing anti-

cal both in its original form and in its tendency to disappear and reappear frequently over long periods. Moreover, this typical exanthem is associated with almost complete absence of other symptoms or signs in the majority of cases

Treatment

No treatment is necessary or would be of any effect.

Epidemiology

From the earliest described cases it has been recognized that the disease occurs in epidemic form. The incubation period appears to be from 6 to 14 days Morbidity is high in exposed groups, and over 50 per cent of exposed children of 12 years or under may be expected to show symptoms Adult cases occur but with less frequency, presumably because of previous exposure Both sexes are equally affected Infection with this viral exanthem does not protect against rubella or any other recognized viral disease

Control Measures

No special control measures are indicated

A very alarming complication of eczema infantum . . . is an acute outbreak of numerous vesicles, partly scattered and partly arranged in groups. The vesicles are as large as a lentil, filled with clear serum, and the majority are umbilicated They look like varicella vesicles but undoubtedly do not belong in this class . . The patients have high fever, —40° C or more, and are very restless The vesicles develop very acutely (sometimes overnight), in large numbers and often continue to appear in successive crops, for three or four days, or even a week. Those which appear first undergo dessication, rupture and expose the corium or they become encrusted and fall off The largest number of the varicella-like vesicles are found upon the already excematous skin but smaller groups appear on the previously intact skin of the neighborhood The outcome of the peculiar affection is in the majority of cases favorable

This excellent description of a typical case requires only a few additions Severity of the disease may vary widely but tends to be severe in patients under 1 year In some the skin shows only mild vesiculation with minimal systemic symptoms and clears in a few days (Jackson and Dudgeon, 1951) In severe infections vesicles can continue to appear for as long as 9 days, and great areas of skin may be denuded of epithelium through which the patient loses large quantities of fluid, electrolytes and protein Death may occur from untreated dehydration, secondary bacterial infection or shock due to adrenal necrosis (Brain et al , 1957) It is striking to note the absence of itching during the attack and its return after healing has taken place

Infrequently, involvement of the eczematous skin may be a manifestation of recurrent disease In such patients serious systemic involvement is largely prevented by circulating antibodies, even though the local lesions may be extensive (Boake et al , 1951)

Traumatic Herpes

Primary infection occasionally occurs through traumatic breaks (burns, abrasions) in the normal skin of a susceptible child and results in a characteristic illness About 2 or 3 days after the original trauma, the skin lesion becomes erythematous, and vesicles appear The child develops fever, If the trauma is on a limb, crops of vesicles on an erythematous base appear centripetally, probably through lymphatic channels, during the course of the next week, and the regional lymph node becomes enlarged and tender The picture has to be differentiated from that of herpes zoster with its dermatome distribution The illness may last from 10 days to 3 weeks before all lesions have disappeared Herpetic stomatitis has been reported as occurring during the course of the illness, Following recovery, vesicles or even large bullae (Findlay and MacCallum, 1940) are likely to recur at the site of original injury Primary infection of apparently unbroken skin has been reported (Scott et al , 1952)

Diseases of the Mucous Membranes

Acute Herpetic Gingivostomatitis

(SYNONYMS: Acute infectious gingivostomatitis, aphthous stomatitis, catarrhal stomatitis, ulcerative stomatitis, Vincent's stomatitis)

This is the commonest manifestation of primary infection While its peak incidence is between 1 and 3 years, it can occur in older children and adults but it seldom if ever occurs below the age of 12 months During the ages of greatest incidence it is probably the most frequent cause of clinical stomatitis The chief characteristics, which are essentially the same for all ages, are as follows fever, irritability, red swollen gums, a vesicular eruption on the mucous membranes of the mouth, oral fetor and local lymphadenopathy (Scott et al , 1941) In about a third of the cases, the onset is insidious, the child being febrile for 2 or 3 days before a sore mouth develops, in the remainder, there is early refusal to eat or actual complaint of sore mouth A constitutional reaction is always present but varies in severity, a high fever, from 104 to 105° F, is not uncommon Visceral involvement has been demonstrated by liver biopsy in a severe case (Tolentino and Matteis, 1953). Lesions in the mouth vary in size and number and are essentially vesicular, although typical vesicles are rapidly modified by maceration and appear as shiny grayish-yellow plaques representing collapsed vesicles with edematous roof cells These often ulcerate before healing No portion of the oral lining is immune, although the tongue and the cheeks are most commonly involved In

bodies against herpes virus, and that recurrent herpes only occurred in those with neutralizing antibodies Since these findings appeared to be contrary to the usual pattern of infectious disease, and since herpes did not seem to spread from patient to patient but seemed to be provoked by some nonspecific stimulus, such as fever, Doerr (1938) suggested "that herpes is not an infectious agent which is maintained by a chain of infection but that it is endogenously generated in the human organism."

These difficulties were resolved when it was shown by Dodd et al (1938) that herpes virus could be routinely isolated from the mouths of infants suffering from a common form of stomatitis, and by Burnet and Williams (1939) that such infants also developed neutralizing antibodies during convalescence from the stomatitis

Following this, similar proofs of a primary herpetic infection were presented by Seidenberg (1941) and Ruchmann et al (1947) for eczema herpeticum; Slavin and Gavette (1946) for vulvovaginitis, Gallardo (1943) for keratoconjunctivitis and Smith et al. (1941) and Armstrong (1943) for meningoencephalitis. As a result it is now recognized that the herpes virus acts like any other infectious agent in the primary infection of a susceptible host On the host's recovery it appears to become latent in the tissues where it can cause local damage under circumstances altering the host's physiology, despite the presence of antibodies in the circulation.

Clinical Picture

The characteristics of the virus result in 2 types of clinical herpetic disease: (1) primary infections with the virus, occurring in persons without neutralizing antibodies in their blood stream; (2) recurrent disease, occurring in persons with such neutralizing antibodies In a primary infection, the local lesion is usually accompanied by a systemic illness that is often severe and sometimes fatal, whereas the patient with a recurrent attack is as a rule singularly free from systemic symptoms, however severe the local lesion may be Serologic surveys have shown that many more adults have circulating antibodies than can be accounted for by a history of clinical infections This means that the majority of infections are subclinical, only an estimated 10 per cent of primary infections causing clinical illness (Scott, 1957). Recovered individuals from a manifest or a subclinical infection may become carriers of the virus Following nonspecific stimuli, such as fever, menstruation, or emotional upsets, these are apt to have recurrent manifestations of herpetic infection.

The clinical manifestations of herpetic infection may be considered under various disease categories: (1) of the skin, (2) of the mucous membranes, (3) of the eye, (4) of the central nervous system, (5) disseminated infections. Most of these present a clinical picture which can usually be recognized. The virus can be isolated readily from typical visible lesions and sometimes from the saliva of an asymptomatic carrier (Buddingh, et al, 1953). Reported isolation of virus from patients with other clinical pictures must be reviewed in the light of a possible superinfection of damaged tissue by this ubiquitous virus.

Diseases of the Skin

Herpes Simplex (Synonyms: Herpes labialis, facialis, febrilis)

This commonest manifestation of recurrent disease, often involving a mucotaneous junction presents as follows: There is a sensation of irritation or burning at the site involved lasting a few hours Reddish papules then appear which quickly vesiculate When fully developed the lesion consists of one or more areas of grouped thin-walled vesicles on an erythematous base The vesicles quickly become purulent, scab and heal without a scar, unless traumatized Recurrences tend to affect the same area of skin time after time In contrast, when the skin is affected in a primary infection, as, for instance, of the chin of an infant with herpetic stomatitis, the vesicles are widely scattered and single Occasionally, lesions recur in a zosterlike distribution (Slavin and Ferguson, 1950), sometimes with an associated lymphangitis (Trice and Shafer, 1953).

Eczema Herpeticum (Lynch, 1945) (Synonyms: Kaposi's varicelliform eruption, Juliusberg's pustulosis vacciniformis acuta)

This is usually a manifestation of a primary infection in which the skin of the eczematous patient is the portal of entry. The clinical description of this disease by Kaposi in 1887 remains good today (Kaposi, 1895):

small dendritic ulcers, or a vesicle appears, often near the lower border of the cornea, which enlarges in a series of branching processes to form the typical "dendritic" ulcer characteristic of herpetic infection. If untreated, this will continue to increase in size to involve large areas of the epithelium, resulting in a "geographic" ulcer with uneven branching edges Although corneal ulceration may occur in either primary or recurrent disease, the diagnostic differentiation may be suspected clinically, since follicular conjunctivitis, an invariable accompaniment of the primary infection, is only rarely present in the recurrent disease Occasionally, indolent, deep, nonbranching marginal ulcers occur in the recurrent disease These leave a clear rim of uninvolved peripheral cells which are protected by the humoral antibodies in the limbic vessels Large erosions of the cornea may recur in healed areas due to weak adhesion between epithelium and Bowman's capsule In the presence of corneal involvement the acute phase usually subsides in 2 to 3 weeks, although some keratitis may persist for several weeks longer

Deep Forms (Thygeson and Kimura, 1957) In contrast with herpetic infections elsewhere, lesions of the cornea, perhaps because of its avascular structure, almost always involve the stroma, tend to be chronic and are accompanied by scarring The clinical pictures are as follows

Disciform Keratitis This may be benign with edema but not necrosis of the stromal fibers, run a definite course of 2 to 3 months and heal with minimal scarring It may follow a clearly demonstrable or an insignificant superficial lesion More commonly it is severe, with necrosis and sometimes rupture of the cornea followed by healing, with dense scar formation, only after many months or even a year Secondary bacterial infection is an almost invariable accompaniment Absence of pain is characteristic because of the hypalgesia of the cornea in herpetic infections Sometimes the disciform process may extend to involve the whole corneal stroma (herpetic interstitial keratitis)

Hypopyon Keratitis This may follow large "geographic" ulceration, particularly after the use of steroids It must be differentiated from that following deep bacterial and fungal ulcerations, by noting the corneal anesthesia in herpetic in contrast with the pain associated with bacterial or fungal ulcers

Iridocyclitis. This may complicate both disciform and hypopyon keratitis. It is characterized by severe pain, circumcorneal flush and multiple keratic precipitates. Synechia formation and secondary lens opacification are frequent Recurrences may occur following fever or other trigger mechanism without accompanying keratitis

The management of these patients should be directed by an ophthalmologist Of great importance is the observation that steroids used either topically or generally, cause increase in severity and frequency of the deep forms of the disease The only specific therapy recommended for restoration of sight to patients with scarred corneae, subject to recurrent disease, is removal of the diseased tissue and replacement by a corneal transplant

Diseases of the Central Nervous System

Herpetic Meningo-encephalitis Herpetic infection of the central nervous system may cause the clinical picture of aseptic meningitis or of acute encephalitis with coma, ocular palsies, paresis of muscle groups, sensory changes and convulsions When evidence of increased intracranial pressure is found the mortality is high death occurring between the 8th and the 12th days (Whitman et al 1946) About 5 to 7 per cent of meningoencephalides are caused by the virus (Afzelius-Alm, 1951, Adair et al, 1953) The mechanism of spread to the nervous system is not clear Hunt and Comer (1955) report a case in which there is suggestive evidence of propagation along nerve axons An etiologic diagnosis can be suspected on clinical grounds if a characteristic stomatitis or lesions on the skin are present A definitive diagnosis can be made only by laboratory means

Associated with Trigeminal Neuralgia. Recurrent attacks may occur at the time of, or a few days after, an attack of trigeminal neuralgia in the area of distribution of the 2nd and the 3rd divisions of the nerve They are frequent after operative section of

some patients the tonsillar region is affected early. Under these circumstances the lesions must be distinguished from those of herpangina due to Coxsackie virus, nonbacterial exudative pharyngitis due to several adenoviruses and bacterial tonsillitis The unilateral tonsillar ulcers of Vincent's angina, which is not herpetic (Steigman and Scott, 1947), can easily be differentiated. Involvement of the gums is characteristic but varies in intensity; sometimes there is only a thin red line along the dental margin which may be the initial evidence of an herpetic stomatitis in a febrile child; sometimes the gums are extensively swollen In the rare infant, infected before the eruption of teeth, the gums escape involvement Submaxillary lymphadenopathy of varying degree is extremely common The disease is self-limiting in about 1 to 2 weeks Pain tends to disappear before the lesions heal. Scarring is absent or very slight Swelling of the gums and lymphadenopathy, among the first signs to appear, usually persist for some days after the ulcers heal

Recurrent Stomatitis

The oral, in contrast with the genital, mucous membranes do not consistently manifest recurrent lesions, although sometimes these can be found on the inner lip, adjoining gum or, *rarely*, more wide-spread during a recurrent attack of herpes labialis (Farmer, 1956) Nevertheless, a history of recurrent stomatitis should weigh against a diagnosis of herpes Recurrent aphthae are as a rule not due to herpes (Blank et al, 1950, Dodd and Ruchman, 1950). Recurrent nonspecific ulceration as a manifestation of *erythema multiforme* may follow 7 to 10 days after a recurrent attack of herpes labialis

Acute Herpetic Rhinitis. The nose may be the site of primary infection, manifested, in the nostrils, by tiny vesicles surrounded by red areolae, enlarged anterior cervical lymph nodes, and fever (Ruchman and Dodd, 1950)

Herpetic Involvement of the Genitalia

FEMALE. These may show primary or recurrent lesions In a primary infection vesicles appear on the mucous membranes of the labia (both majora and minora) and the lower vagina These are quickly modified, as in the mouth, resulting in scattered lesions covered with gray-yellow membranes Accompanying these are local pain, enlarged regional nodes, low-grade fever and sometimes vesicular lesions on the adjacent skin The lesions heal in the course of 1 to 2 weeks. The recurrent disease shows similar lesions (Slavin and Gavette, 1946).

MALE. Primary infection is apparently very uncommon. It has taken the form of a nonbacterial urethritis, with burning pain on micturition and either a watery or a purulent discharge. Tiny vesicles have appeared on the glans or the prepuce. No regional lymphadenopathy has been reported. In one case a generalized cutaneous hyperesthesia, mainly of the lower limbs, accompanied the peak of the illness, which lasted about 2 months A concurrent herpetic stomatitis was present in one case (Slavin, 1951; Esteves and Pinto, 1952) Recurrent attacks (*Herpes progenitalis*) are quite common and consist of a cluster of erosions (eroded vesicles) on the glans, or the corona, sometimes associated with herpetic vesicles on the shaft of the penis

Diseases of the Eye

Herpetic Keratoconjunctivitis and Keratitis

Herpetic infection of the eye is a serious hazard to sight Clinically, the infection can be confined to the superficial or can involve the deep structures of the eye As in other sites, the clinical manifestations may be due to primary or recurrent disease

SUPERFICIAL FORMS (Braley, 1957, Ormsby, 1957). These are characteristic of acute herpetic keratoconjunctivitis, which is usually a manifestation of primary herpetic infection occurring chiefly in children and adolescents The disease usually begins as a unilateral conjunctivitis with accompanying preauricular lymphadenopathy and malaise It may be associated with a vesicular eruption on the lids or a stomatitis There is a follicular conjunctivitis, with some chemosis and edema of the lids Ulcers of the conjunctiva sometimes are seen The infection may be confined to the conjunctiva, in which case the disease clears up in a few days The cornea may be involved in two ways. There is either an early diffuse epithelialitis, resulting in superficial punctate erosions which later develop into

lesions inclusion bodies are found In the lungs, in addition to this picture, Pugh et al (1955) have described a peculiar type of necrosis, basophilic in character and consisting mainly of deoxyribonucleic acid, which they ascribe to intense local necrosis with rapid breakdown of cells The area is sharply demarcated from the adjacent tissues which show intense congestion and infiltration with mononuclear cells

The pathologic changes in the nervous system occur mostly in the cortex with progressively less involvement of the central white matter and the basilar structures Grossly, there are focal areas of dusky discoloration, studded with petechiae, which are swollen and friable Histologically, there is widespread mononuclear infiltration of the leptomeninges The lesions in the cortex are characterized by intense degeneration and mild inflammation The appearance suggests encephalomalacia due to circulatory disturbance Fat-laden phagocytes flood the field, and the capillaries show endothelial hyperplasia Neuronophagia occurs At the margins of necrotic areas, hypertrophied microglial cells and mild astrocytosis are seen There is perivascular cuffing with mononuclear cells Inclusion bodies may be demonstrated, preferably with phloxine-methylene blue stain, in oligodendria and less frequently in nerve cells (Wolf, 1950)

Experimental Infection, Host Range

The natural host of the virus is man However, it can be transmitted to the following experimental hosts rabbit, guinea pig, mouse, hamster, cotton rat, the embryonated hen's egg and to several types of cells grown in tissue culture of which the most utilized are rabbit kidney, and HeLa and human amnion

In the animal hosts the reaction depends on the route of inoculation of virus When introduced by corneal scarification a keratoconjunctivitis develops in the rabbit and the guinea pig between 12 hours and 7 days, depending on the virulence of the preparation The conjunctiva becomes injected, the cornea cloudy, because of the development of small vesicles along the scratch marks, and an exudate appears, at first watery but later purulent, in which many of the cells are mononuclear, although not predominantly so, and there are no bacteria The nictitating membrane becomes red and swollen The lesion heals slowly over the course of 1 to 2 weeks, leaving a varying amount of residual corneal opacity.

The encephalitis resulting from intracerebral inoculation manifests itself by fever, tremors, lethargy, convulsions and weakness of muscle groups Death usually ensues, although recovery may take place An entirely comparable encephalitis occurs in the rabbit after the corneal inoculation of certain neurotropic strains Suckling mice 1 to 3 days old are particularly susceptible and die on 5th to the 6th day after intracerebral and intraperitoneal inoculation with weakness, in-coordination and paralysis (Kilbourne and Horsfall, 1951, Lennette and van Allen, 1957) Certain strains produce characteristic lesions in the skin of the rabbit or the foot pads of the guinea pig About 2 days after an intradermal inoculation a red papular lesion develops which may vesiculate and then subsides after 2 to 3 days

The embryonated hen's egg is a very susceptible host Inoculation onto the chorioallantoic membrane of 11- to 13-day-old eggs gives rise to characteristic pocks which appear as early as the 20th hour but are best examined after incubation at 36° C from the 36th to the 48th hours The pocks are small, 1 to 2 mm in diameter, white, often oval and sometimes with tails, raised above the ectoderm Central necrosis and mesodermal reaction may be seen in old lesions, but these are not very conspicuous in contrast with the lesions of vaccinia (Beveridge and Burnet, 1946) Histologic examination of an early pock, 20 hours after inoculation, reveals that it consists of a heap of proliferated cells, 90 per cent of which contain Fuelgen positive inclusions filling the nuclei During the ensuing 72 hours the following changes occur the epithelial cells slough, remaining inclusions become shrunken, the mesoderm shows an inflammatory reaction and some inclusion bodies and, finally, the entoderm becomes thickened by cell proliferation (Crouse et al, 1950)

The blastoderm of 1-day-old eggs is equally susceptible, after infection the blastoderm ceases to develop, but virus continues to be formed over the course of 5 days (Yoshino, 1956).

Inoculation of virus into the yolk sac of 9-day-old eggs causes death of the embryo

the nerve It is not certain whether the virus lies latent in the nerve tissue or the skin, but more likely the latter (*Carton and Kilbourne*, 1952; Behrman and Knight, 1954).

Disseminated Herpes

Viremia has been demonstrated occasionally in severe cases of primary herpetic infection (Ruchmann and Dodd, 1950), and evidence of infection of the liver has been found in children with stomatitis (Tolentino and Matteis, 1953, Zuelzer and Stulberg, 1952) Therefore, it is not surprising that occasionally widespread clinical manifestations of the infection appear.

Neonatal. There have been several reports of a fatal infection in newborns (Quilligan and Wilson, 1951; Zuelzer and Stulberg, 1952, Pugh et al., 1954; Williams and Jack, 1955). The illness may start between the 4th and the 7th days after birth, with vesicles on *the skin, a stomatitis or a conjunctivitis.* Following this, the infant becomes seriously ill with high fever, dyspnea, evidence of encephalitis, and jaundice and dies within a few days. Death with generalized symptoms of pulmonary, liver or central nervous system disease may occur without any evidence of superficial herpetic infection At autopsy hepatic necrosis is a striking and sometimes the only finding; cells in the vicinity of the necrotic areas contain intranuclear inclusions In other patients similar intranuclear inclusions have been found in the endothelium of the blood vessels, lungs, spleen, kidneys, adrenals and brain. Herpes virus has been isolated from the liver of several such patients Death may occur from a secondary septicemia of *Ps. pyocyanea* The pathogenesis of these infections is obscure The infant may be exposed to virus from the mother, suffering a primary infection around the time of delivery, or, if born of a mother without antibodies, to virus from an attendant, either a carrier or with a recurrent lesion. Prematurity seems to play a role, the exact nature of which is not known.

Adults. Kilbourne and Horsfall (1951) described 2 adults with symptoms suggestive

initially diagnosed as suffering from smallpox because of severe systemic illness and a widespread rash (Kipping and Downie, 1948).

Pathologic Picture

Details of the pathologic picture vary with the type of infected tissue In general, the characteristic change induced by the virus is the intranuclear inclusion body first described by Lipshutz, 1921. The development of the inclusion body appears to be a dynamic occurrence. One or more areas of Feulgen-positive material appear between strands of condensed chromatin, these coalesce to form a Feulgen-positive homogenous body. This appears bluish with routine hematoxylin and eosin stains and fills the nucleus, compressing the c

shrir

nega

by a halo from the marginated chromatin (Crouse et al., 1950, Wolman and Behar, 1952) This is now the classic Type A inclusion body of Cowdry, 1934.

Pathologic changes in the skin and the mucous membranes are characterized by vesicle formation In the latter the vesicle is modified by early maceration and leakage of fluid These changes take place in the

characteristic multinucleated giant cells, leukocytes and fibrin Each giant-cell nucleus contains an inclusion body These giant cells are of diagnostic aid and can be recognized in a smear from the base of a fresh vesicle. The infected epithelium at the edge of the vesicle can be distinguished from the normal skin by the presence of proliferation, "ballooning degeneration" and intranuclear inclusions The mucosal lesion resembles the skin lesion except for the relative absence of fluid, greater amount of fibrin and edematous thickening of the roof-cells in the former. The corium of both skin and mucous membrane shows pronounced capillary dilatation and infiltration of inflammatory cells but no necrosis, which accounts for the usual absence of scarring.

In disseminated infection many viscera are involved, the liver and the adrenals show *coagulation necrosis involving not only parenchymal* cells but also stroma and blood vessels with little cellular inflammatory response. In the cells at the periphery of these

medium through breaks in the cell membrane These double membrane particles, representing mature virus, measure 120 to 130 mμ in diameter (Morgan et al, 1954) It would appear from the above and from other circumstantial evidence that *Herpesvirus hominis* is released from the infected cell by a slow leak rather than by disruption of the cell

Latency. This is a characteristic of the virus in vivo Pelmont and Morgan (1958) have reproduced this in vitro, in that when infected HeLa cells are carried in a deficient medium the virus can no longer be detected but becomes demonstrable again when the nutritional deficiences are corrected

Antibody Response Complement-fixing neutralizing and skin-test antibodies are formed by the intact host. After primary infection these first two appear between 4th and the 6th days, reaching their height by the 14th day In children the antibody titer may drop to undeterminable levels after the first infection (Buddingh et al, 1953), only to be boosted by a series of subclinical or possibly clinical reinfections

Preservation The activity of the virus is temperature dependent in that a strain may have a ½ life of 5 hours at 37° C and 24 hours at 30° C Inactivation at 37° C is increased when the pH of the medium is outside the range of 6 8 to 7 4, especially in the lower ranges (Stoker, 1958) Activity is also destroyed by lipid solvents such as ether and fluorocarbon, and by phosphatases It can be preserved in whole tissue in 50 per cent glycerol, or at −70° C in the presence of stabilizers such as skim milk, serum or egg yolk (Scott, 1956)

By adulthood the CF and neutralizing antibody levels in a given individual have usually been stabilized As a result they do not vary with the clinical appearance of recurrent disease, although rises may occur in an occasional individual Skin test antibodies appear to parallel the other two between the ages of 10 and 50 years but are inconsistent at the extremes of life (Scott, 1957)

Diagnosis

This is based on the combination of a characteristic clinical picture and a positive laboratory diagnosis The latter consists of (1) the isolation of the virus from a lesion or a tissue of the patient as a result of inoculation into a susceptible host, (2) the demonstration of a rise in antibodies during convalescence from a primary infection (the neutralization antibody is the most constant); (3) the demonstration of virus-giant cells in scrapings from the base of a fresh lesion (Blank et al, 1951), or (4) demonstration of inclusions in tissue sections

Infections by this virus must be differentiated from those by several other viruses While the laboratory must provide the final answer, there are certain helpful clinical criteria as follows.

1 *Eczema Herpeticum from Eczema Vaccinatum* In the former, vesicles appear in crops so that the rash shows lesions of different stages at any given time while in the latter they tend to be all at the same stage In the latter there is almost always a history of exposure to vaccinia while in the former there may be a cold sore in one of the contacts The same criteria can be applied to the differentiation between *herpetic and vaccinal vulvitis*

2 *Herpetic Keratoconjunctivitis from Epidemic Keratoconjunctivitis (Adenovirus Type 8)* The latter is painful whereas relative anesthesia of the cornea is characteristic of the former A history of recurrences, the presence of typical dendritic ulcer and vesicles on the lids are also characteristic of the former

3 *Acute Herpetic Gingivostomatitis from Herpangina (Coxsackie Group A Viruses) and Nonbacterial Exudative Pharyngitis (Adenoviruses)* This may be particularly difficult in those cases in which the herpetic infection begins in the fauces, which is the characteristic place for the lesions of Herpangina However, in the latter the lesions do not spread to other portions of the buccal mucosa which are eventually involved in the herpetic infection and the course of Herpangina is much shorter (4 to 6 days) than that of herpetic stomatitis Herpangina is a summer disease, and there is a frequent history of contact, while herpetic infection occurs at all seasons, and usually there is no history of contact (Parrott et al, 1954). Suspicion of adenovirus infection may be supported if there are present conjunctivitis or generalized lymphadenopathy

after an incubation period of about 48 to 72 hours

Infected rabbit kidney cells in culture undergo the following changes: Cytoplasmic granulation appears, and the cells become rounded and refractile, "balloon" cells, multinucleate giant cells appear, in which the nuclei may be pyknotic or contain inclusion bodies; finally, areas of lysis occur (Sosa Martinez et al, 1955) Rather similar changes are described for HeLa cells (Scherer and Syverton, 1954) Human amnion cells show much the same response. The giant cells arise largely from cell fusion and may contain hundreds of nuclei, each containing an inclusion body (Stoker, 1958).

The strain of virus used may determine whether clumping and apparent pock formation, or giant cells and lysis occur predominantly (Gray et al, 1958) Rabbit kidney tissue culture sheets can be used for quantitating the virus, since infected areas appear as white plaques when the culture is stained with neutral red (Kaplan, 1957)

Etiology

Appearance and Size. The electron-microscopic appearance is that of an inhomogenous sphere with a dense center However, in some particles derived from egg or vesicle fluid the center appears less dense and almost absent, resulting in doughnut-shaped forms (Coriell et al, 1950) Filtration through gradocol membranes revealed an average diameter of 100 to 150 mμ (Elford et al, 1933) while Munk and Akerman (1953) suggested a diameter of 96 mμ based on calculations [illegible]

and Hunt, 1954) and different genetic markers (Wildy, 1955)

Course of Infection. In HeLa cells the following stages have been described (Stoker, 1958). Adsorption occurred slowly, about 50 per cent being adsorbed in 1 hour and 80 per cent by 2 hours By the end of 2 hours about half the absorbed virus had entered the cell and inhibited mitosis; an eclipse phase then ensued, the length of which depended on the amount of virus entering the cell but was not less than [redacted] hours. With the electron microscope viral particles in large numbers could be seen attached to the cell surface during the eclipse phase which could be removed by specific antisera or EDTA, new virus particles appeared in the nucleus at 12 hours, and large numbers were present in the cytoplasm and on the cell surface by 26 hours Free virus appeared in the medium by 15 hours; this corresponded to the formation of about 100 particles per cell by 50 hours In addition, it seemed clear that some form of virus could spread from cell to cell without entering the medium.

DNA increased 40 per cent in the nuclei of infected cells during the eclipse phase when no recognizable particles were seen under the electron microscope and was almost double the normal quantity by 72 hours The source of this DNA is not clear, since it is more than could possibly be of viral origin even if herpes virus were a DNA virus, which is not yet known (Newton and Stoker, 1958).

These findings are in general agreement with the less detailed observations reported after infection of the C A M where the rate of adsorption was somewhat more rapid, 50 to 80 per cent being adsorbed in 15 minutes, and the eclipse phase lasted 7 to 12 hours This was followed by a logarithmic release of infectious virus into the medium over the next 10 to 12 hours (Scott et al, 1953b)

In the C.A M it would appear that 1 infectious virus particle was equivalent to 1 pock-forming unit (Yoshino and Taniguchi, 1956)

Relation of Virus to Intranuclear Inclusion Body. The nature of the inclusion body now appears to be established as an accumulation of developing virus particles The eclipse period corresponds to progressive changes in the nucleus up to the development of an inclusion that fills the nucleus At this time infectious virus is again detectable Thereafter, virus gradually leaves the nucleus, and the classic Type A inclusion represents a virus-free residue (Scott et al, 1953a, Lebrun, 1956). Under the electron-microscope, dense particles measuring 30 to 40 mμ, appear in the infected nucleus These enlarge and acquire a single membrane reaching the size of 70 to 100 mμ. Larger particles with 2 surrounding membranes then seem to make their way into the cytoplasm through breaks in the nuclear membrane and into the

medium through breaks in the cell membrane These double membrane particles, representing mature virus, measure 120 to 130 mμ in diameter (Morgan et al, 1954) It would appear from the above and from other circumstantial evidence that *Herpesvirus hominis* is released from the infected cell by a slow leak rather than by disruption of the cell

Latency. This is a characteristic of the virus in vivo Pelmont and Morgan (1958) have reproduced this in vitro, in that when infected HeLa cells are carried in a deficient medium the virus can no longer be detected but becomes demonstrable again when the nutritional deficiences are corrected

Antibody Response. Complement-fixing, neutralizing and skin-test antibodies are formed by the intact host After primary infection these first two appear between 4th and the 6th days, reaching their height by the 14th day In children the antibody titer may drop to undeterminable levels after the first infection (Buddingh et al, 1953), only to be boosted by a series of subclinical or possibly clinical reinfections

Preservation The activity of the virus is temperature dependent in that a strain may have a ½ life of 5 hours at 37° C and 24 hours at 30° C Inactivation at 37° C is increased when the pH of the medium is outside the range of 6 8 to 7 4, especially in the lower ranges (Stoker, 1958) Activity is also destroyed by lipid solvents such as ether and fluorocarbon, and by phosphatases It can be preserved in whole tissue in 50 per cent glycerol, or at −70° C in the presence of stabilizers such as skim milk, serum or egg yolk (Scott, 1956)

By adulthood the CF and neutralizing antibody levels in a given individual have usually been stabilized As a result they do not vary with the clinical appearance of recurrent disease, although rises may occur in an occasional individual Skin test antibodies appear to parallel the other two between the ages of 10 and 50 years but are inconsistent at the extremes of life (Scott, 1957)

Diagnosis

This is based on the combination of a characteristic clinical picture and a positive laboratory diagnosis The latter consists of (1) the isolation of the virus from a lesion or a tissue of the patient as a result of inoculation into a susceptible host; (2) the demonstration of a rise in antibodies during convalescence from a primary infection (the neutralization antibody is the most constant); (3) the demonstration of virus-giant cells in scrapings from the base of a fresh lesion (Blank et al, 1951), or (4) demonstration of inclusions in tissue sections

Infections by this virus must be differentiated from those by several other viruses While the laboratory must provide the final answer, there are certain helpful clinical criteria as follows

1 *Eczema Herpeticum from Eczema Vaccinatum* In the former, vesicles appear in crops so that the rash shows lesions of different stages at any given time while in the latter they tend to be all at the same stage In the latter there is almost always a history of exposure to vaccinia while in the former there may be a cold sore in one of the contacts The same criteria can be applied to the differentiation between *herpetic and vaccinal vulvites*

2 *Herpetic Keratoconjunctivitis from Epidemic Keratoconjunctivitis (Adenovirus Type 8)* The latter is painful, whereas relative anesthesia of the cornea is characteristic of the former A history of recurrences, the presence of typical dendritic ulcer and vesicles on the lids are also characteristic of the former

3 *Acute Herpetic Gingivostomatitis from Herpangina (Coxsackie Group A Viruses) and Nonbacterial Exudative Pharyngitis (Adenoviruses)* This may be particularly difficult in those cases in which the herpetic infection begins in the fauces, which is the characteristic place for the lesions of Herpangina However, in the latter the lesions do not spread to other portions of the buccal mucosa which are eventually involved in the herpetic infection and the course of Herpangina is much shorter (4 to 6 days) than that of herpetic stomatitis Herpangina is a summer disease, and there is a frequent history of contact, while herpetic infection occurs at all seasons, and usually there is no history of contact (Parrott et al, 1954) Suspicion of adenovirus infection may be supported if there are present conjunctivitis or generalized lymphadenopathy

4. Herpetic Meningo-encephalitis from the Numerous Other Viral Encephalitides This is almost impossible in most instances The epidemiologic history may be some guidance in ruling out certain other viruses such as the arthropod-borne group, or the patient may show other signs of herpetic infection

Treatment

There is no specific treatment, and the clinical manifestations of the disease are self-limited However, nonspecific supportive therapy must be utilized in primary infection to preserve life in some instances and in recurrent infection to give symptomatic relief and, in eye infections, to preserve sight

Primary Infections. Severe stomatitis may lead to dehydration in infants because of lack of intake This must be combated by appropriate parenteral fluid and electrolyte replacement Intake of fluid and food must be encouraged, cold semisolids like ice cream are often better tolerated than plain liquids at room temperature Local anesthetics before feeding may be helpful in older children Prevention of secondary bacterial infection may be aided by the frequent use of mouth washes such as Ceepryn 1 : 4,000 or a freshly prepared suspension of chlortetracycline, 1 to 3 per cent, in 10 per cent glycerine containing 100,000 units of Nystatin per ml. This can be used to swab the mouths of infants. Systemic penicillin in prophylactic doses may be useful in the younger children where local therapy is difficult

Severe eczema herpeticum requires meticulous attention Parenteral replacement of the fluid, electrolytes and protein lost through the denuded skin is required Anticipation of a secondary bacterial infection requires appropriate and sustained antibiotic therapy based on culture results Local care of the skin requires removal of crusts by soaks, and application of nonsensitizing antibiotics, e g , chloramphenicol, in a hydrophilic ointment base. When there is a severe systemic reaction, steroids *in full doses for a few days may tide* the patient over a crisis Gamma globulin has [illegible] *of the disease* by providing antibodies.

Encephalitis. A patient with herpetic encephalitis must be managed according to the principles utilized in the case of any acute encephalitis

Recurrent Infection. The occasional recurrent vesicle can be treated with local measures. Drying agents, such as alcohol, or Ceepryn 1:4,000, are useful for early application to lesions of the lips or the skin, followed by a broad-spectrum antibiotic ointment (e g , Neosporin). Permanganate sitz baths provide cleanliness and comfort for vulval lesions. The patient that is plagued with very frequent recurrences, unassociated with a clearly recognizable trigger mechanism may require psychotherapy (Blank and Brody, 1950). The application of superficial x-rays is not justified The use of repeated courses of smallpox vaccination has a widespread current vogue but seems to have little theoretical basis Beneficial results are reported by some, but not all, observers The mechanism is unknown and may possibly be based on suggestion Vaccination with herpes virus, either dead (Anderson et al , 1950) or living, is theoretically unsound and practically useless It may be hazardous if live virus is used (Lazar, 1956).

The treatment of eye lesions should be under the supervision of an ophthalmologist. This consists of cauterization and scraping of the corneal ulcer, prevention of secondary bacterial infection by means of topical antibiotic or chemotherapeutic applications and keratoplasty in hopelessly damaged corneae.

Epidemiology

Two separate population groups have to be considered (1) those without circulating antibodies who are susceptible to primary infection, and (2) those with circulating antibodies who are liable to recurrent disease (Scott, 1957).

Primary infection. Pertinent factors may be classified under 3 heads: (1) *Socio-economic and environmental.* It was early noted that the incidence of infection was considerably higher among persons in a lower than those in a higher socio-economic bracket. The amount of overcrowding and the level of public health education appear to increase and decrease, respectively, the incidence in a given population. (2) *Age.* The number of

immunes in a population, as measured by the presence of detectable humoral antibodies, varies with age. The percentage of immune newborns is the same as that of the adults but decreases to a low level between the ages of 6 months and 2 years, thereafter increasing to that of the adult population by about the age of 5 years. The incidence of clinical disease is greatest between 1 and 3 years. For unexplained reasons herpetic stomatitis is almost unknown under 1 year, although eczematous infants of less than 1 year not infrequently suffer an attack of eczema herpeticum. (3) *Reservoir of Infection*. This must be largely among subclinically infected carriers, since actual contact with a clinical infection is relatively rare, being variously estimated from 10 to 50 per cent. It has been demonstrated that patients completely recovered from stomatitis may excrete virus in their saliva intermittently for as long as 7 weeks and that virus can be isolated from the saliva of 2.5 per cent of asymptomatic adults. It can also be isolated from the stools.

Incubation period. Evidence from various sources suggests a range between 2 and 12 days with a peak at 4 days.

Epidemics. As noted earlier, this is an endemic disease with about 90 per cent of the infections being subclinical. However, under exceptional circumstances epidemics can occur, (1) in families in which more than one member may be affected either at the same time from a common source or in sequence, (2) in a hospital ward where patients with eczema can be infected following the admission of a case of eczema herpeticum, (3) in institutions as, for example, one in which 20 of 36 infants under 22 months developed herpetic stomatitis and 16 had subclinical infection (Anderson and Hamilton, 1949).

Mechanism of Spread. This appears to be by contagion in which spread is favored by overcrowding, and the close bodily contact that occurs in infancy, and among adults in kissing and sexual intercourse. Trauma appears to be an important trigger mechanism in establishing a clinical infection in a susceptible individual.

Recurrent Disease. The basic stimulus for the appearance of a recurrent lesion is not a reinfection from without but a disturbance in the physiology of the host which activates a latent virus. This may be induced by a change in (1) the external environment, such as exposure to ultraviolet rays or (2) the internal environment, such as produced by fever, menstruation, nerve injury, or emotion.

Control Measures

There are no specific control measures apart from generally accepted standards of hygiene. It is particularly important for persons suffering from atopic eczema to avoid exposure, and patients with eczema herpeticum must be rigidly isolated. For the susceptible adult, sexual contact in some form probably provides the greatest risk of primary infection.

HERPESVIRUS SIMIAE
(Synonym: B virus)

History

In 1934 Sabin and Wright reported the isolation of this virus from the brain of a laboratory worker dying 18 days after the bite of an apparently normal *Macacus rhesus* monkey. It was found to be immunologically related to the viruses of herpes simplex and pseudorabies (Sabin, 1934). A second fatal case was diagnosed in 1949 (Sabin, 1949). Since that time a number of laboratory workers have been infected, the virus being isolated from their central nervous system, or their blood showed a significant rise of specific antibodies. It has also been isolated from the nervous system of "normal" monkeys and from monkey kidney cells in tissue culture (Wood and Shimada, 1954, Melnick and Banker, 1954).

Clinical Picture

The clinical features of the patients observed have shown the same variability expected in any central nervous system infection. Thus there have been symptoms and signs of (1) acute encephalitis with headache, vomiting, early coma and early death with evidence of increased intracranial pressure but little else abnormal on neurologic examination, (2) encephalomyelitis with excitement, confusion or delirium, and sometimes hypertension, cranial and spinal nerve involvement resulting in diplopia, nystagmus, patchy paresthesia of head, neck and upper extremities, hiccough, myoclonic spasms of trunk muscles with terminal generalized weakness and coma, (3) myelitis with paresthesia and paralysis of lower extremities and bladder, the mind remaining clear until the ascending process leads to respiratory failure. Meningeal symptoms have been inconspicuous. A mild lymphocytic pleocytosis in spinal fluid has been

4. *Herpetic Meningo-encephalitis from the Numerous Other Viral Encephalitides* This is almost impossible in most instances The epidemologic history may be some guidance in ruling out certain other viruses such as the arthropod-borne group, or the patient may show other signs of herpetic infection

TREATMENT

There is no specific treatment, and the clinical manifestations of the disease are self-limited However, nonspecific supportive therapy must be utilized in primary infection to preserve life in some instances and in recurrent infection to give symptomatic relief and, in eye infections, to preserve sight.

Primary Infections. SEVERE STOMATITIS may lead to dehydration in infants because of lack of intake This must be combated by appropriate parenteral fluid and electrolyte replacement. Intake of fluid and food must be encouraged, cold semisolids like ice cream are often better tolerated than plain liquids at room temperature Local anesthetics before feeding may be helpful in older children Prevention of secondary bacterial infection may be aided by the frequent use of mouth washes such as Ceepryn 1 4,000 or a freshly prepared suspension of chlortetracycline, 1 to 3 per cent, in 10 per cent glycerine containing 100,000 units of Nystatin per ml This can be used to swab the mouths of infants Systemic penicillin in prophylactic doses may be useful in the younger children where local therapy is difficult

SEVERE ECZEMA HERPETICUM requires meticulous attention Parenteral replacement of the fluid, electrolytes and protein lost through the denuded skin is required Anticipation of a secondary bacterial infection requires appropriate and sustained antibiotic therapy based on culture results. Local care of the skin requires removal of crusts by soaks, and application of nonsensitizing antibiotics, e g, chloramphenicol, in a hydrophilic ointment base When there is a severe systemic reaction,

of the disease by providing antibodies

ENCEPHALITIS A patient with herpetic encephalitis must be managed according to the principles utilized in the case of any acute encephalitis.

Recurrent Infection. The occasional recurrent vesicle can be treated with local measures. Drying agents, such as alcohol, or Ceepryn 1:4,000, are useful for early application to lesions of the lips or the skin, followed by a broad-spectrum antibiotic ointment (e g, Neosporin). Permanganate sitz baths provide cleanliness and comfort for vulval lesions The patient that is plagued with very frequent recurrences, unassociated with a clearly recognizable trigger mechanism may require psychotherapy (Blank and Brody, 1950) The application of superficial x-rays is not justified. The use of repeated courses of smallpox vaccination has a widespread current vogue but seems to have little theoretical basis Beneficial results are reported by some, but not all, observers The mechanism is unknown and may possibly be based on suggestion Vaccination with herpes virus, either dead (Anderson et al, 1950) or living, is theoretically unsound and practically useless It may be hazardous if live virus is used (Lazar, 1956).

The treatment of eye lesions should be under the supervision of an ophthalmologist This consists of cauterization and scraping of the corneal ulcer, prevention of secondary bacterial infection by means of topical antibiotic or chemotherapeutic applications and keratoplasty in hopelessly damaged corneae

EPIDEMIOLOGY

Two separate population groups have to be considered. (1) those without circulating antibodies who are susceptible to primary infection, and (2) those with circulating antibodies who are liable to recurrent disease (Scott, 1957).

Primary infection Pertinent factors may be classified under 3 heads: (1) *Socio-economic and environmental.* It was early noted that the incidence of infection was considerably higher among persons in a lower than those in a higher socio-economic bracket. The amount of overcrowding and the level of public health education appear to increase and decrease, respectively, the incidence in a given population. (2) *Age. The number of*

Etiology

Appearance and Size. The virus measures about 125 mμ as determined by filtration through gradocol membranes. Under the electronmicroscope, particles appear spherical with a dense center. The early particles have 1 membrane and measure 60 to 100 mμ in diameter, while mature virus has 2 membranes and measures 120 to 180 mμ.

Course of Infection. Reissig and Melnick (1955) have demonstrated that after inoculation of monkey kidney tissue culture the virus disappears from the supernatant medium over the course of 8 hours and becomes detectable again at about the 12th hour. Under the electronmicroscope particles with 1 or 2 membranes appear in both nucleus and cytoplasm. Particles with similar size and structure appear on the surface of the cells at the time infectious virus is detectable in the medium.

Preservation. It can be preserved in 50 per cent glycerol, at −70° C. and by lyophilization.

Antibody Response. The virus has a close antigenic relationship to *Herpesvirus hominis* and a lesser one to *Herpesvirus suis*. An antiserum against *Herpesvirus simiae* neutralizes *Herpesvirus hominis* as well as or better than it neutralizes itself, whereas an antiserum against *Herpesvirus hominis* will not neutralize *Herpesvirus simiae* or only to a very low titer (Burnet et al., 1939; Sabin, 1934).

Diagnosis

An encephalomyelitis developing after contact with monkeys should be considered clinically to be due to this virus until proved otherwise. Isolation of the virus from infected central nervous tissue is the only definite diagnostic criterion. This may be difficult, especially if the patient has lived for some time. Diagnosis can be made, based on a rise in antibody levels in patients who survive for more than 10 days, since a rise of neutralizing antibodies equally against this virus and *Herpesvirus hominis* occurs. The convalescent titer is low against both. In herpetic infection the titer rises, usually to a higher level, only against *Herpesvirus hominis* (Sabin, 1958). The presence of circulating antibodies against *Herpesvirus hominis* does not prevent fatal infection with *Herpesvirus simiae* (Nagler, 1957).

Treatment

In view of the absence of specific therapy, the usual supportive measures employed for a patient with encephalitis assume major importance. It would seem advisable to give steroids in pharmacologic doses for several days as soon as the diagnosis is made. One patient in whom recovery took place began to get better following such therapy (Breen et al., 1958).

Epidemiology

"Normal" monkeys are the reservoir of the virus. Infection can be acquired through bites and apparently by contamination of normal or minimally traumatized skin by monkey saliva or tissues. Contamination of a wound by infected monkey kidney tissue culture cells has resulted in a fatal infection in a man without actual contact with monkeys (Hummeler et al., 1958).

Control Measures

Great care should be taken by those handling monkeys to avoid exposure of naked skin to contact with any secretion or tissue. No vaccine is yet available.

usual but may be absent; sugar and protein usually have been normal, the pressure has been normal except in the case with the acute encephalitis *The white count has been within* normal limits. Acute abdominal pain, fever and diarrhea have been presenting symptoms in some patients before onset of neurologic signs. Fever has usually but not always characterized the infection. In two bitten patients the local wounds showed redness and swelling with purulent exudate in one and neighboring vesicles in the other The incubation period has been between 10 and 20 days The illness has usually ended in death after a course of 1 day to over 3 weeks from onset of symptoms (Hummeler et al, 1958, Pierce et al, *1958*, Lennette, *1957*, Nagler, *1957*; *Pavilanis, 1957; Sabin, 1949, Sabin and* Wright, 1934) An occasional recovery has been reported but with considerable residual disability *(Breen et al, 1958)*

Pathology

In human material extensive involvement of the brain and the spinal cord has been found The vessels showed perivascular cuffing with mononuclear cells and sometimes necrosis of the walls Necrosis of all elements occurred in some places and the areas appeared demyelinated Satellitosis and neuronophagia were present Intranuclear inclusions were found on occasion in patients dying early in the disease but usually were not observed. The meninges showed vascular engorgement and mononuclear cell infiltration

In the other organs focal necrosis was found in spleen, lymph nodes and adrenals, and cloudy swelling in liver and kidneys In monkeys suffering from a natural primary infection (Keeble *et al*, 1958) *perivascular* cuffing and infiltration with glial cells occurred largely in the roots of the facial and the trigeminal nerves Intranuclear inclusions were found with difficulty in the oligodendrial cells *in the region of perivascular cuffing. Livers* showed varying degrees of damage, from necrosis about the central veins to periportal infiltration of polymorphonuclear and mononuclear cells Intranuclear inclusion bodies were *readily found in relation to the larger* areas of damage. The characteristic tongue ulcers (cf. herpetic ulcers in man) consisted of two zones—a central area of necrosis and a surrounding area of ballooning degeneration; between *these two*, cells with intranuclear inclusion bodies were most readily found, either as single cells or as coencytic masses ("Virus" giant cells). Immediately beyond the area *of ballooned cells the normal epi*thelial cells showed enlargement of the nucleoli

In the rabbit the pathology has been described by Sabin and Hurst (1935). In general the changes resemble those in the monkey. However, when the virus is inoculated intradermally it causes local necrosis and spreads to the central nervous system. This is apparently by way of the peripheral nerves in which an interstitial neuritis occurs.

Experimental Infection, Host Range

This virus is a natural parasite of monkeys in the same way as *Herpesvirus hominis* is a *natural parasite of man. An outbreak of stom*atitis among monkeys due to this virus, entirely comparable with herpetic stomatitis in *man, has been described (Keeble et al, 1958)* The incidence was 2 3 per cent among 1,400 rhesus monkeys In 25 per cent of affected animals there was histologic, even in absence of clinical, involvement of the central nervous system. Antibodies developed on recovery. Among normal monkeys in a colony antibodies have been found in approximately 20 per cent This incidence may rise to 75 to 100 per cent after the animals have been housed together over a period of 6 weeks (Kretch and Lewis, 1954; Keeble et al, 1958; Prier, 1958). The virus can be transmitted readily to rabbits by any route, usually *with a* fatal outcome. Mice are susceptible but only if under 3 weeks of age, in contrast with *Herpesvirus hominis* which can infect older *animals (Sabin, 1958)* 1-day-old chicks have been infected by intracerebral inoculation (Reagan and Bruckner, 1953). It grows readily on the chorio-allantoic membrane of the embryonated hen's egg, producing pocks similar to those of *Herpesvirus hominis*, and egg-adapted strains kill the embryo in 6 days, focal lesions being found in the viscera Rabbit kidney cells are very susceptible and both HeLa and monkey *kidney cells can be in*fected. The cells swell, the nucleoli disappear, the chromatin becomes marginated, and an inclusion body develops; giant cells containing many infected nuclei then begin to appear

Varicella—Herpes Zoster Group

(SYNONYM FOR VARICELLA Chickenpox SYNONYMS FOR HERPES ZOSTER Zona, shingles, zoster)

INTRODUCTION

On the basis chiefly of clinical and epidemiologic data the writer suggested in the previous editions of this book the probability of the identity of viral agents in the etiology of these clinical diseases or syndromes as also had a number of other observers The more recent fundamental studies of Weller (1953) have added sound evidence in the same direction It has become more clearly apparent that these clinical syndromes probably are but 2 phases in the activity of a single virus of uniform antigenic composition without known strain differences, which may be termed the varicella-zoster, or VZ, virus Therefore, in this chapter Varicella and Zoster will be considered as 2 phases of a single disease

Varicella is a mild communicable disease or syndrome confined chiefly to children It is characterized by fever and an itching, vesicular eruption of the skin and the mucous membranes, individual lesions of which are surrounded by erythema

Herpes zoster, which is a severely painful and incapacitating infectious syndrome confined chiefly to adults, is characterized by inflammation of dorsal-root ganglia or extramedullary ganglia of cranial nerves accompanied by crops of vesicles, identical with those of varicella, in areas supplied by affected sensory nerves

HISTORY

The severity of pain and the characteristic localization of both pain and vesicles made the diagnosis and the study of zoster far simpler than varicella, since the latter was generalized and in early medical history was not easily differentiated from smallpox

Zoster was described very early in medical literature and was known to the Greeks as zona Von Barensprung, 1862a, b, 1863, first recorded observations relating the area of skin involved by eruption to its corresponding dorsal-root ganglion In 1884, Landouzy (Levaditi, 1926) on clinical grounds, suggested its infectious nature Head and Campbell, 1900, furnished a classic description of the neuropathology, while Lipschutz, 1921, described the histopathologic changes in the vesicles In 1888, von Bokay, 1909, suggested its possible relation to varicella and later recorded many cases in point, Kundratitz, 1925, inoculated human subjects and apparently obtained some successful takes

Varicella was not described as a clinical entity until the era of Sydenham, it was confused with smallpox until the end of the 18th century Steiner, 1875, experimentally demonstrated it to be infectious. Tyzzer, 1906, described the pathologic response in varicella and provided an excellent picture of the localized lesion Paschen, 1917, described ele-

mentary bodies in the vesicular fluid and suggested a virus as the etiologic agent.

CLINICAL PICTURES

The clinical pictures of varicella and zoster are best understood if varicella is recognized as the primary invasion of an individual by the VZ virus with the resultant generalized *infection but with occasionally a superimposed zosterlike localization of signs* Zoster, occurring separately from varicella, may best be considered as the localized reinvasion by the virus of an immune host or the stimulation to activity of a virus (VZ virus) remaining latent in the human host following its primary invasion as varicella. Thus the localization of zoster could be a reactivation *of the virus latent in the posterior* nerve roots or ganglia by means of an insult such as exposure to cold, pressure, leukemia, or a fresh massive dose of virus Except on rare occasions when a few vesicles erupt over other skin areas, the reactivation or reinvasion remains localized, probably as *the result of a general immunity produced* by the primary varicella invasion

VARICELLA

The incubation period is usually from 14 to 16 days; occasionally, it may be as long as 21 days Approximately 24 hours after the onset of fever, crops of papules, *followed* or accompanied by vesicles with surrounding erythema, appear on the face and the trunk, spreading usually to the mouth, the pharynx and the extremities In chickenpox, the lesions are usually most abundant over the trunk, *while the face and the extremities suffer the most damage from smallpox* Occasionally, the generalized eruption will be accompanied by a localized eruption characteristic of zoster. The eruption occurs simultaneously with the fever, and its duration is proportional to the height and the persistence of the latter. Successive crops of lesions appear, *furnishing all the characteristic stages of* papules, vesicles and crusts at the same time over the affected areas There is a general lymphadenopathy, which is particularly noticeable in the suboccipital and the posterior cervical regions when vesicles occur in the scalp The vesicles, which are indistinguishable from those of zoster, frequently become pustular and the crusts are often removed by *scratching* because of itching. Impetigo, furuncles, septicemia and glomerulonephritis may complicate the picture. Vesicles on the laryngeal mucosa, about the eyes and the genitalia and in the hair present difficult problems The encephalitis, which occasionally complicates varicella, is symptomatically similar to that accompanying zoster but is less common and less severe than that oc*curring in measles Occasionally, neuritis* of the cranial nerves or myelitis may occur. Even temporary blindness may complicate the picture. Small, depressed, white scars may result from severe varicella or a secondary infection of vesicles with pathogenic bacteria No significant changes occur in the number and the character of the blood cells

Pneumonitis occurs in very severe or fatal *cases, particularly in adults, and* radiologically presents a characteristic bilateral nodular infiltration A fatal nodular pneumonitis has been occurring more recently in persons who have contracted varicella while receiving steroid therapy which greatly diminishes resistance, Cheatham et al. (1956)

ZOSTER

The difficulty in establishing an incubation period for zoster may be better understood in the light of this syndrome's apparent status as a reactivation of a localized latent virus (VZ virus) or as a reinvasion of the vi*rus in the posterior nerve root areas,* as mentioned above. Thus the predilection for the posterior nerve root areas may be a quality of viral latency or a tissue susceptibility to reinvasion or both. The author has established from a number of personal observations and more recently from additional observations of a number of clinicians that zoster in adults resulting from exposure to varicella appears usually within 3 to 7 days after exposure to varicella—a reaction closely resembling the accelerated response of a par*tially immune person to vaccinia virus* While the incubation period of zoster secondary to varicella may often be accurately determined, in zoster secondary to tumors or other insults the incubation period obviously would be indeterminable, nor would it be of any significance. Zoste

severe pain, fever, malaise and often exquisite tenderness along the dorsal nerve roots and their corresponding skin areas The pain may be generalized over the area supplied by the nerve or may be sharply localized to the point of nerve exit close to the spine or to the midaxilla where the nerve divides into a deep and a superficial branch

It may be secondary to an insult to a susceptible dorsal nerve root, such as that caused by arsenic, tuberculosis, tumor leukemia, or it may appear without apparent cause At times abortive zoster occurs in which only an erythematous patch appears over the area involved without vesiculation It is rarely bilateral Early in the disease, the lymph node draining the involved area is usually large and tender A crop of papules, rapidly becoming vesicles, appears within 3 or 4 days after onset over the skin supplied by affected nerves and may continue to appear occasionally for 2 or 3 weeks There are also occasionally aberrant vesicles which may be so numerous at times that they simulate the eruption of varicella Vesicles may become pustular if secondarily infected with bacteria As crusts form, pain and tenderness usually disappear Extensive involvement of a ganglion may affect motor roots or it may extend to anterior horn cells, resulting in temporary or permanent paralysis The dorsal roots of the trunk are most frequently involved, while next in frequency are the areas supplied by the 2nd to the 4th cervical ganglia, i e, the shoulders, the arms and the neck Finally, the lower extremities and the perineal area, in that order, are affected least frequently Inflammation of the maxillary division of the trigeminal nerve will produce lesions in the uvula and the tonsillar area, while similar lesions in the anterior part of the tongue, the mouth floor and the buccal mucosa result from involvement of the mandibular division Zoster ophthalmicus follows involvement of the ophthalmic division, which may be particularly serious with resulting scleritis, keratitis and iridocyclitis, ulcers of the cornea and the conjunctiva may occur Vesicles on the pharynx, the tongue, the uvula and the larynx may be extremely painful, laryngeal and faucial paralysis are not infrequent In approximately 50 per cent of cephalic cases of zoster, paralysis occurs When the geniculate ganglion is involved, pain in the auditory canal is followed by a vesicular eruption on the pinna and in the external canal Facial paralysis frequently results, which on rare occasions is permanent Rare involvement of the otic ganglion results in deep pain of the fauces on the affected side, combined with a few vesicles in this area and on the uvula There is usually a mild lymphocytosis in the spinal fluid, unless the number of cells is markedly increased by meningo-encephalitis which is an occasional complication Persistent neuralgia following convalescence in older subjects is common

PATHOLOGIC PICTURE

In contrast with the vesicle of variola which exhibits a reticular degeneration of the prickle-cells, the vesicles of varicella and zoster are obviously the result of a ballooning of the cells with very little reticulation In the early stages, nuclei of infected cells contain the spheroidal and eosinophilic inclusion bodies described by Tyzzer, 1906, in varicella and by Lipschutz, 1921, in zoster In the process of nuclear degeneration, these bodies apparently enter the cytoplasm so that they may be seen simultaneously in nuclei and cytoplasm While in early stages of the development of lesions some proliferation of the epidermis occurs, the corium remains practically unaltered Later, amitoses of the prickle-cells with formation of sickle-shaped, multinuclear cells, the ballooning of cells with their subsequent disintegration, and the entrance of tissue fluids result in the typical vesicle In some large vesicles, the corium may form the base, and in such cases all layers of the skin may be involved, and scarring may result

There are several reports (Johnson, 1940) of young infants having died of varicella A complete postmortem examination was made on one by Johnson (1940), who found characteristic lesions in the esophagus, pancreas, liver, renal pelvis, ureters, bladder and adrenal glands Intranuclear inclusions were present in the endothelium of blood vessels, and at times necrosis of the vessel walls occurred Cellular changes, including intranuclear inclusions, in the visceral lesions were similar to those seen in the skin

Zoster, in addition to skin lesions, produces a characteristic inflammatory reaction in the posterior nerve roots and ganglia Rarely, the

inflammation spreads to the anterior horns, resulting in temporary or permanent paralysis. In the posterior root, there is infiltration of small round cells and red blood cells, necrosis of nerve cells and fibers, and an inflammatory reaction of the ganglion sheath. It has been shown (Ebert, 1949) that zoster can cause destruction of sensory nerve fibers from the corium. The corresponding fibers of the spinal cord undergo degeneration In severe cases, scarring is found in the involved ganglionic area, with loss of cells and nerve fibers and thickening of the ganglion sheath, while in milder cases little or no permanent damage occurs. The dorsal ganglia more often involved, as shown by Head and Campbell, 1900, are those that receive fibers from the viscera through the white ramus of the sympathetic branches

EXPERIMENTAL INFECTION, HOST RANGE

Despite experiments by Eckstein (1933), the results of which indicate that monkeys may be infected by the varicella-zoster virus, there is no conclusive evidence that any host other than man is susceptible. Intranuclear inclusion bodies were found in the tubular cells of monkey testes by Rivers (1926) 5 or 6 days after intratesticular injection of varicella virus in young vervets and green monkeys. Typical varicella lesions in the skin were not produced Steiner, 1875, produced varicella in children by inoculating them experimentally with fluid from varicella vesicles. This work has been fully confirmed by others Zoster vesicular fluid also has induced varicella in experimental human subjects as well as local vesicles more characteristic of *zoster. Evidence of propagation of zoster virus* in human skin grafted on the chorio-allantois of chick embryos was obtained by Goodpasture and Anderson (1944) and Blank et al. (1948), although the chick-embryo tissues themselves appeared to be nonsusceptible. The lesions obtained resembled those of the natural disease with intranuclear inclusions in affected epithelial cells.

More recently Weller (1953) has been able to obtain serial propagation in vitro of the varicella-zoster virus with roller tube cultures of human embryonic skin-muscle tissue and with foreskin tissue obtained from boys between 3 months and 3 years. Both varicella and zoster vesicle fluids were used successfully for the inoculations. Nutrient fluid in the cultures was changed at 3- to 4-day intervals. Typical eosinophilic nuclear inclusions were obtained, and from the focal areas of affected cells peripheral extension of infection to contiguous cells over days or weeks occurred. For subcultures it was necessary to use coarsely ground infected tissue rather than centrifuged fluids from the cultures

ETIOLOGY

Electronmicrographs (Rake et al, 1948; Nagler and Rake, 1948) showed that viral bodies from vesicles of varicella and zoster are, as a rule, brick-shaped and identical in appearance and size (210 to 250 mμ). By the same means it was also demonstrated that zoster viral particles agglutinated in the presence of serum collected from patients convalescent either from zoster or from varicella Vesicles 12 hours old contain numerous viral particles, while those 24 hours old yield very few.

Early laboratory studies, using vesicle fluids and cutaneous crusts as antigens, all suffered from the lack of a virus antigen grown in cultures Nevertheless, a close antigenic relationship was established by the studies of several workers (Rivers and Eldridge, 1929a, b; Amies, 1934) in neutralization, complement-fixation and agglutination tests More recently, the roller tube cultures of virus from both varicella and zoster by Weller (1957) have permitted more critical analysis of the antigens by complement-fixation, neutralization and fluorescent antibody tests (Weller and [illegible] plement fixa-tion [illegible] harve[illegible] *bottle cultures* afforded an excellent antigen. The tests carried out by plate drop method of Fulton and Dumbell (1949), as modified by Svedmyr et al (1952), strongly suggested the identity of varicella and zoster viruses Their identity was also apparent in neutralization tests conducted on virus cultures to which acute and convalescent sera from varicella and zoster patients were added as 10 per cent of the nutrient medium (Weller, 1956). Finally, no detectable antigenic differences were found when cultures of vari-

cella and zoster viruses were prepared on cover slips and treated appropriately with acute and convalescent varicella and zoster sera and then overlayered with antihuman gamma globulin prepared in rabbits and labeled with fluorescein In these tests antibody appeared in zoster and varicella convalescent sera to an almost identical degree By these important methods of antigenic analysis the identity of the viruses of varicella and zoster thus far studied seemed to be fairly well established. The antibodies appear within 4 to 7 days after onset and reach a peak in about 3 weeks with a subsequent slow decline

Also, clinical data on the similarities of the 2 syndromes since von Bokay's original observations show the following relationships

Varicella in children more often induces zoster in exposed adults than it does in exposed children

Zoster, whether in children or adults, rather frequently has been observed as the apparent source of varicella in children (almost never in adults), initiating at times large epidemics The number of such recorded incidents is too great to be explained satisfactorily on the basis of chance alone Varicella and zoster not infrequently occur at the same time in the same child

Certain careful studies, such as those made by The School Epidemics Committee (1938) of Great Britain in a large number of boarding schools, have shown that varicella and zoster occur during the same terms more frequently than is likely to be due to chance and apparently are not seasonal

Despite certain contradictory evidence, zoster occurs frequently in children and adults who previously have had varicella, thus indicating a lack of complete resistance to the virus as a result of previous experience with varicella Zoster and varicella usually produce lasting immunity

Zoster vesicular fluid has been used experimentally to inoculate children intradermally with some success in the production of varicella, Kundratitz, 1925 This has been confirmed (Bruusgaard, 1932) by a second human passage which resulted in a contact infection

In at least 2 isolated island communities, zoster has been observed, whereas no cases of varicella have ever been recorded.

A working hypothesis to relate the above observations may be useful Such a hypothesis could consider the varicella virus as infecting the general population almost universally at an early age A generalized infection with the virus with a relatively long incubation period may permit the development of permanent resistance However, in certain cases, the varicella virus may have neurotropic properties, as indicated by the simultaneous development at times of zoster and varicella, and it may remain within the nerve cells of a few individuals in a manner similar to the symbiosis exhibited by herpes simplex virus and ectodermal cells In adult life, exposure to cold, pressure on a nerve, or a fresh massive dose of varicella virus (in epidemic parotitis, heavy exposure of a resistant individual may at times disturb the parotid without generalized symptoms) may cause a localized virus activity along posterior root fibers with subsequent development of zoster vesicles Zoster produces varicella with greater difficulty and less frequency than does varicella itself This may be explained by the ease of spread of virus from varicella lesions in the mouth and the throat whereas the virus in zoster skin lesions is usually well covered and without a ready means of transport The absence of varicella and the presence of zoster in isolated communities may possibly represent the activity of an endemic neurotropic varicella virus (zoster virus) with which the population has been universally infected but which becomes apparent in relatively few or it may represent the seeding of the virus soon after birth in an inapparent infection

It is still possible, although not at all probable, in view of the newer serologic studies that the viruses of varicella and zoster are distinct entities, possessing certain antigenic constituents in common The growth in tissue cultures and the serologic studies of a greater number of strains of virus should soon resolve this question

DIAGNOSIS

The lesions of herpes simplex may at times be confined to a nerve distribution in the skin, in which case inoculation of vesicular

fluid into suckling mice appears to be the simplest method of differentiation, inasmuch as herpes simplex virus will infect the mice, whereas zoster virus will not. Otherwise, little difficulty should be experienced in differentiating zoster from herpes simplex. Varicella and herpes zoster are frequently indistinguishable. The severe constitutional reaction caused by smallpox with a drop in fever as the rash appears, together with uniformity of development of the eruption in all areas of the skin at the same time and the somewhat larger number of vesicles on the extremities, as compared with the trunk, serve *to distinguish this disease from varicella. Also* in smallpox the lesions tend to be deeper, "shotty" and umbilicated.

TREATMENT

The vesicles of herpes zoster and varicella require similar care to prevent secondary infection, and similar treatment of secondary infections when they occur Oral or parenteral administration of sulfonamides or appropriate antibiotics, and the local application of tyrothricin are useful when the invading bacteria are sensitive to these therapeutic agents Cleanliness of the skin, care of the hands, cutting and cleaning fingernails, and local treatment for relief of irritation and itching and for the prevention of secondary bacterial infections are important measures. In addition, zoster lesions may require sedative ointments, such as 1 per cent cocaine in lanolin. Deep x-ray therapy may also be effective when used early in the disease For late neuralgia, section of sensory roots may be necessary

EPIDEMIOLOGY

20 years, whereas zoster is a disease of extremely low incidence Varicella attacks the sexes equally, *while zoster has a slightly* higher incidence in males, which may be accounted for by the more frequent exposure of older males to severe climatic conditions. Contact infections occur rarely in zoster, while varicella spreads more readily than most infectious diseases, perhaps more readily than measles. Much of the dissemination of varicella is through the air. It may result from the inhalation of small amounts of air by a susceptible person in any enclosed space con-

frequently in the winter and the spring.) Frequency of the recurrence of varicella epidemics depends upon the density of susceptibles; the recurrence rate is lower in rural than in urban populations, acting in this respect in a manner similar to that of measles.

If zoster is an expression of latency of the varicella-zoster virus, as suggested here and in previous editions, as well as by Garland (1943), rather than a reinvasion of virus by infection from an external source, this may well represent, as in herpes febrilis, an example of the immune host becoming an agent of viral spread and viral propagation—an important epidemiologic model for which there must be many others in man.

CONTROL MEASURES

No control measures are available for herpes zoster as it occurs in sporadic form. Convalescent serum is apparently of little, if any, value for protection against varicella, and of no value in its treatment. Transplacental immunity apparently is not present in the newborn. There is available no method of active immunization Under school or institutional conditions, partial disinfection of the air by means of ultraviolet light has limited the epidemic spread of varicella. As a rule, isolation *and quarantine are useless, inasmuch* as the spread of varicella apparently occurs most readily before the disease is clinically manifest. The crusts appear to be infectious while still moist, but dry crusts apparently have lost their infectivity. Thus, if isolation is warranted, 7 days should be sufficient.

Mumps

(SYNONYM: Epidemic parotitis)

INTRODUCTION

Mumps is an acute, self-limiting contagious disease with a high morbidity and a very low mortality. The most constant feature is a painful enlargement of the parotid gland Involvement of other organs is not uncommon, and usually there is a constitutional reaction indicative of a generalized infection

HISTORY

Mumps ■ one of the first diseases which were recognized as clinical entities. In the 5th century B.C., Adams, 1891, its most common manifestations were clearly recorded by Hippocrates, who described it as a mild epidemic sickness characterized by nonsuppurative swellings near the ears and occasionally accompanied by painful enlargement of the testes In modern times, Hamilton, 1790, was among the first to stress orchitis as a frequent manifestation of the infection He also noted certain patients suffering from parotitis who showed symptoms referable to the central nervous system However, it was not until the beginning of the 20th century that clinically apparent and inapparent meningo-encephalitis was generally recognized as a complication. Thereafter it also became evident that other organs, e g, the ovary and the pancreas, might be injured by the infectious agent (Wesselhoeft, 1941). During the first decades of the present century considerable effort was expended in attempts to determine the etiologic agent. Various reports appeared incriminating a variety of bacteria as well as a spirochete, but it was not until 1934 that the causative agent was definitely proved to be a filterable virus (Johnson and Goodpasture, 1934).

CLINICAL PICTURE

Eighteen to 21 days usually elapse between exposure and the development of symptoms, in exceptional cases the period of incubation may be 12 days, or less, or as long as 35 days Infection of the salivary glands is manifested by a varying degree of enlargement. The parotids are those most frequently involved In more than 70 per cent of patients the swelling is bilateral, although one gland may become enlarged first, and after from 1 to 5 days the other may show an increase in size. Pain is usually present when gland enlargement is marked, when such is not the case, pressure on the angle of the jaw may cause pain in the region of the gland. Enlargement of the submaxillary and the sublingual glands is not uncommon and is best determined by palpation. Edematous infiltration of the tissues surrounding the salivary glands is a frequent event and in certain cases may be very marked. Occasionally, presternal edema may be present, a clinical sign that has been recognized only in recent years.

Swelling of a gland usually reaches a maximum within 48 hours and most often persists for 7 to 10 days. Occasionally, some enlargement of the structure still can be discerned after the lapse of several weeks. In the earlier stages a restricted area of redness may be observed immediately about the orifices of the ducts of Stensen and Wharton. Fever of moderate degree may be present 12 to 24 hours before swelling is observed and usually persists from 1 to 3 days. In certain cases it may be absent.

The following is a list of most of the other organs which have been mentioned in the literature as exhibiting signs of involvement: testis, epididymis, prostate, ovary, liver, pancreas, spleen, thyroid, kidneys, labyrinth, eye, thymus, heart (myocardium), vulvovaginal glands, mammary glands (male and female) and nervous system (as manifested by symptoms of encephalitis, encephalomyelitis, neuritis of the facial, trigeminal and optic nerves). In general, it must be emphasized that certain of these structures may be affected not only before or after the parotitis as well as synchronously with it, but even when there is no indication of inflammation of the salivary glands. Furthermore, it should be noted that the frequency with which certain of these organs are attacked has varied widely among several groups that have been studied. Most commonly, the testes or the central nervous system is involved. Orchitis develops on the average once in every 5 cases of parotitis occurring in mature males, although wide variations from this mean may be expected in different outbreaks. In spite of this incidence, sterility resulting from mumps orchitis is rare. This is due in part to the fact that only about one sixth or less of the cases are bilateral and that atrophy of all glandular tissue may not ensue, even in the severe cases (Werner, 1950). An even greater variation in the frequency of meningo-encephalitis, ranging from 0.5 to 10 per cent of the cases of parotitis, has been reported by various observers. There are reports that aseptic lymphocytic meningo-encephalitis unassociated with parotitis but due to mumps virus may occur more frequently in the summer than in the spring (Ritter, 1958). If so, the difficulty of making a clinical diagnosis of mumps meningitis during the summer is increased.

Epididymitis, prostatitis, ovaritis and pancreatitis of marked intensity are noted more rarely. Studies have revealed a regular elevation of serum amylase in patients with simple parotitis as well as parotitis with overt pancreatitis (Zelman, 1944; Applebaum, 1944). An increase in this enzyme does not therefore necessarily indicate pancreatic involvement (Warren, 1955).

The total white blood cell count is variable in different patients, at times being either moderately elevated or depressed and at others within normal limits. The differential count often shows an absolute or relative increase in lymphocytes from the 1st to the 14th day of the illness, but this phenomenon is by no means invariable. Obviously, blood leukocyte counts are of little aid in diagnosis. In contrast with the blood, the white cell count of the spinal fluid is of great significance in the diagnosis of the general syndrome of aseptic lymphocytic meningo-encephalitis, of which mumps virus is one of the known etiologic agents. In mumps encephalitis the number of white cells of the fluid is increased. The total count may range from 8 to 10 cells (normal) to more than 2,000 per cu mm. In one series of 11 cases, the mean count was 434 (Kane and Enders, 1945). In a majority of cases, the proportion of lymphocytes is from 90 to 100 per cent (Kilham, 1949). When determining the significance of an increased white count in the spinal fluid reports should be borne in mind which indicate that in as many as 35 per cent of the cases of simple parotitis presenting no clinical signs of central nervous system involvement the leukocyte count of the cerebrospinal fluid is greater than normal (Bang and Bang, 1943).

Although long suspected on the basis of epidemiologic data, it was not long ago that serologic evidence was obtained which indicates that infection with the virus of mumps may be so innocuous that symptoms do not occur or at least are so mild as to escape observation (Maris et al., 1946). Thus, specific complement-fixing antibody has been found in the blood of one half or more of the tested adults who denied having had mumps (Penttinen et al., 1954). Even in groups of children which have been studied, the number of inapparent infections based on

Mumps

(SYNONYM: Epidemic parotitis)

INTRODUCTION

Mumps is an acute, self-limiting contagious disease with a high morbidity and a very low mortality The most constant feature is a painful enlargement of the parotid gland. Involvement of other organs is not uncommon, and usually there is a constitutional reaction indicative of a generalized infection

HISTORY

Mumps is one of the first diseases which were recognized as clinical entities In the 5th century B C, Adams, 1891, its most common manifestations were clearly recorded by Hippocrates, who described it as a mild epidemic sickness characterized by nonsuppurative swellings near the ears and occasionally accompanied by painful enlargement of the testes In modern times, Hamilton, 1790, was among the first to stress orchitis as a frequent manifestation of the infection He also noted certain patients suffering from parotitis who showed symptoms referable to the central nervous system However, it was not until the beginning of the 20th century that clinically apparent and inapparent meningo-encephalitis was generally recognized as a complication Thereafter it also became evident that other organs, e g, the ovary and the pancreas, might be injured by the infectious agent (Wesselhoeft, 1941). During the first decades of the present century considerable effort was expended in attempts to determine the etiologic agent. Various reports appeared incriminating a variety of bacteria as well as a spirochete, but it was not until 1934 that the causative agent was definitely proved to be a filterable virus (Johnson and Goodpasture, 1934)

CLINICAL PICTURE

Eighteen to 21 days usually elapse between exposure and the development of symptoms, in exceptional cases the period of incubation may be 12 days, or less, or as long as 35 days. Infection of the salivary glands is manifested by a varying degree of enlargement The parotids are those most frequently involved. In more than 70 per cent of patients the swelling is bilateral, although one gland may become enlarged first, and after from 1 to 5 days the other may show an increase in size Pain is usually present when gland enlargement is marked; when such is not the case, pressure on the angle of the jaw may cause pain in the region of the gland Enlargement of the submaxillary and the sublingual glands is not uncommon and is best determined by palpation. Edematous infiltration of the tissues surrounding the salivary glands is a frequent event and in certain cases may be very marked. Occasionally, presternal edema may be present, a clinical sign that has been recognized only in recent years

tion reaction, chicken or human erythrocytes being used, or the complement-fixation reaction. In suspended fragment cultures of chick amnion, Weller and Enders (1948) demonstrated multiplication of the virus as indicated by the appearance of specific hemagglutinins in the culture fluid. Henle and Deinhardt (1955) showed that cultures of the HeLa strain of human carcinoma cells and of trypsinized monkey kidney can be applied effectively to the isolation and the propagation of the virus. The virus can be detected directly in the culture by its cytopathic effect and by the hemadsorption technic (Shelokov et al., 1958) or by tests for complement-fixing or hemagglutinating antigens in the culture fluid. Virus neutralization tests in vitro can also be used to demonstrate the agent (Deinhardt and Henle, 1956). A comparative study has shown that the tissue culture is more sensitive than the chick embryo in revealing the presence of virus.

ETIOLOGY

Johnson and Goodpasture (1934) showed that the agent passes readily through Berkefeld V and N filters. A considerable range of particle size and shape is indicated by measurements employing graded collodion membranes (Enders and Habel, 1956) and the electronmicroscope (Weil et al., 1948, Dawson and Elford, 1949). Values from 90 to 340 mμ have been reported. Sedimentation diagrams show two boundaries; the principal one had a constant $S = 1311 \times 10^{-13}$ and the secondary an $S = 1940 \times 10^{-13}$ (Weil et al., 1948). Other properties of the virus to which specific references will be found in the review of Enders and Habel (1956) are as follows: Infective virus particles can be easily concentrated by centrifugation (20,000 rpm for 20 minutes), but concentration of soluble complement-fixing antigen requires a greater force and a longer time (30,000 rpm for 1 hour). Most of the properties of the virus are relatively resistant to heat. Complement-fixing antigen withstands 80° C. for 20 minutes. Infectivity and hemagglutinin can be destroyed by 20 minutes at 55° C., but Kilham (1956) has found certain strains with greater stability of both these properties at 56° C. He also demonstrated infectivity and hemagglutinin of some recently isolated strains after 91 days at room temperature. All the properties of mumps virus can be preserved for at least 1 year if kept in skimmed milk at −50° C. to −70° C. The virus has been reported to be most stable between pH 5.8 and 8.0. Its infectivity can be destroyed without impairing hemagglutinin or complement-fixing antigens by exposure to 0.2 per cent formalin at 4° C. for 24 hours. Intense UV radiation for 0.28 seconds will similarly affect the virus. Ether treatment for 30 minutes at 4° C. will destroy infectivity. By treating virus suspended in synthetic mediums with 0.5 per cent beta-propiolactone for 2 hours at pH 7 the infectivity for chick embryos can be destroyed without affecting hemagglutinating capacity (Polley and Guerin, 1957). The substance giving allergic skin tests in hypersensitive individuals can be heated at 65° C. for 20 minutes without loss of activity and is much more resistant to low concentrations of formalin than the infectivity component (Enders, 1943, 1946).

The virus of mumps has the property of causing agglutination of red cells of certain species (Levens and Enders, 1945), causing the lysis of erythrocytes (Morgan et al., 1948) and bringing about fixation of complement in the presence of specific antibody (Enders and Cohen, 1942) and eliciting a delayed allergic reaction in the skin of human beings who have been previously infected (Enders, 1943). The infective, hemagglutinative and hemolytic properties are closely associated. There appear to be two components capable of fixing complement, the "S" (soluble) and the "V" (viral) antigens. These may be separated either by adsorption on red cells (Enders, unpublished data) or by differential centrifugation (Henle et al., 1947, Henle et al., 1948a). Antibodies which neutralize infectivity, inhibit hemagglutination and fix complement appear in the blood serum after infection with the virus. The relationship of the allergenic factor to the other antigenic properties has not been determined, but, like the immediate reaction to vaccinia virus, a positive reaction to it has been shown to be correlated in most instances with an immune state (Enders et al., 1946a; Henle et al., 1951a). The mumps agent has been

this criterion is considerable, at times approaching that of the adults. The available experimental observations indicate that this antibody arises only in response to an infection with the virus or after its inoculation in an inactive state. A more direct indication for the occurrence of inapparent infections is provided by the findings of Henle et al. (1948b), who isolated the agent between the 14th and the 15th days after exposure from the saliva of 6 of 8 volunteers infected experimentally with mumps virus but who failed to develop any clinical signs of infection.

PATHOLOGIC PICTURE

From the diagnostic point of view, pathologic changes induced by the virus are not usually of assistance. In general, the injury is not extensive, with the exception of that occurring in the testis in severe orchitis. The limited observations on material from infected parotid glands indicate that the reaction consists of a serofibrinous exudate with leukocytes in the connective tissue. The cells of the ducts show evidence of degeneration, and necrotic debris and polymorphonuclear cells are found in their lumina (Dopter and Repaci, 1909) Mumps virus has been recovered at autopsy from parotid tissue in which these changes were observed (Weller and Craig, 1949). Characteristic inclusion bodies have not been described in tissues from infected human beings In the testis there are considerable destruction of the epithelium of the seminiferous tubules, marked congestion, punctate hemorrhages and lymphocytic infiltration. Edema and serofibrinous exudation are present in the interstitial tissues (Smith, 1912; Manca, 1932, Gall, 1947). In the pancreas, evidence of congestion, interstitial edema, slight degeneration of the islets, and fat necrosis have been observed The changes induced by the virus in the central nervous system have not been defined, since in the few cases which have terminated fatally the evidence for mumps virus as the cause of death is not conclusive.

Clinical reports suggest that when mumps

vations in developing chick embryos indicate that the virus can cause a variety of deformities (Hamburger and Habel, 1947; Williamson et al., 1957).

Johnson and Goodpasture (1936) reported finding inclusion bodies in the parotids of experimentally infected monkeys. However, Bloch (1937) considered them to be artifacts In spite of their absence in infected living hosts, Brandt (1958) has recently demonstrated the formation of eosinophilic cytoplasmic inclusions in cultures of chick embryo cells in which multiplication of the virus was demonstrated.

EXPERIMENTAL INFECTION; HOST RANGE

In addition to man the animals known at present to be susceptible to virus recovered from naturally infected human beings include certain species of monkeys (Swan and Mawson, 1943) and the chick embryo (Habel, 1945; Levens and Enders, 1945). Guinea pigs (Bolin et al, 1950), suckling mice (Kilham and Murphy, 1952), suckling hamsters (Burr and Nagler, 1953) and suckling white rats (Pospíšil and Brychtová, 1956) have been infected with egg-adapted virus. The presence of complement-fixing antibodies in normal dog sera has been reported (Morris et al, 1956), suggesting that this species may be susceptible. The susceptible species of monkeys include the rhesus (*Macaca mulatta*), the cynomolgus (*Macaca irus*), the pig-tailed (*Macaca nemestrinus*) and the moor (*Macaca maurus*) Typical parotitis characterized by parotid enlargement, facial edema and pathologic changes closely resembling those found in the affected parotid of man can be produced in monkeys only by directly inoculating the gland via Stensen's duct. By means of this procedure the virus can be demonstrated in saliva obtained from patients. Serial passages in monkeys can be effected by injection of a suspension of the parotid gland removed 4 to 7 days following inoculation.

The virus has been isolated by inoculating the amniotic cavity or the yolk sac of the chick embryo (Beveridge et al, 1946). After several passages the virus becomes well adapted to this host and can be recovered from most of its tissues and fluids after an incubation period of 3 or 4 days or longer Tests for the presence of the agent may be made by employing either the hemagglutina-

body against mumps virus develops rapidly in most patients so that by 1 week after the first clinical signs this substance has emerged in a majority. By the end of the 3rd week, in all cases which have been studied, antibody has been demonstrated. In many persons the antibody may persist in the circulating blood for years, although in a concentration lower than those reached during convalescence. In cases where the first specimen of serum has not been obtained sufficiently early to permit the demonstration of a rise in titer, the finding of titers exceeding 1:64 (initial serum dilution) can be interpreted as suggestive of a recent infection. By testing a single specimen of serum taken shortly after onset of symptoms for complement-fixing antibodies against the "S" and the "V" antigens, an early presumptive diagnosis can sometimes be made, since, as Henle et al. (1948a) have shown, early in the disease the level of antibody reacting with "S" antigen is frequently higher than that of antibody reacting with "V" antigen. The antihemagglutinin compared with complement-fixing antibody tends to persist for a longer time at a higher titer. It should be noted that the skin test is of little or no value in diagnosis, since dermal hypersensitivity develops at widely varying intervals following the onset of mumps. Indeed, it is best not to do a skin test for diagnosis, because production of complement-fixing antibody may be stimulated by this procedure in persons who are not suffering from the disease.

Since all strains of mumps virus so far examined appear to belong to a single antigenic type, the demonstration of mumps antibody by any of the technics mentioned above may be taken, with considerable assurance, as evidence of previous infection with this agent. However, one should bear in mind that following infection with mumps virus certain persons develop antibodies which react with Newcastle disease virus of fowls (NDV). In this connection the antigenic cross relationships with influenza D (Sendai) and the Croup-Associated Viruses should also be recalled.

Diagnosis can also be confirmed by recovery of the etiologic agent, for which tissue culture is at the present time the method of choice. However, isolation procedures are usually more laborious than tests for antibodies which are employed as routine in the laboratory diagnosis of mumps. Mumps virus has been recovered in monkey-kidney-cell cultures from saliva, mouth swabs, urine and cerebrospinal fluid. In one study (Utz et al., 1957), 76 per cent of all specimens collected during the first 5 days of illness contained virus, and urine passed as late as the 13th day yielded the agent.

TREATMENT

The treatment of simple parotitis is symptomatic. In severe orchitis, recourse is sometimes had to surgical procedures for reducing the pressure caused by edema. In encephalitis, if the headache is severe, lumbar drainage may afford marked relief. There are no particular procedures employed in the treatment of the other so-called complications of mumps (Wesselhoeft, 1941). Specific therapy, consisting of the administration of various materials derived from human blood, has been attempted in the case of orchitis and meningitis. Most of the efforts have centered upon the prevention and the treatment of orchitis, the materials have been administered before the onset of orchitis but after swelling of the parotid had appeared as well as during the acute stage of orchitic inflammation. They have consisted of whole blood from recent convalescents, convalescent serum, and concentrates of globulin either from pooled normal adult plasma or from pooled convalescent sera. Results obtained in a limited number of patients in which the treatment of established orchitis or meningitis has been attempted have been equivocal, and indeed it might be anticipated that a procedure of this sort would not prove to be efficacious once the virus had caused cellular injury. On the other hand, there are limited data suggesting that concentrated gamma globulin prepared from the plasma of persons recently convalescent from mumps is of some value in preventing the development of orchitis if given after the onset of parotitis. However, concentrated normal gamma globulin has proved to be of no value under these circumstances (Gellis et al., 1945).

Several steroid hormones have been used in attempts to prevent or treat mumps orchitis

classified among the myxovirus group of animal viruses (Andrewes et al., 1955). Serologic cross-reactions have been demonstrated with other members of this group, notably Newcastle disease virus (Evans, 1954) and influenza D virus (De Meio and Walker, 1957) With Chanock's Croup-Associated Agent a similar relationship seems to exist (Chanock, 1956).

Mumps, in nearly all instances, confers a durable immunity, as is indicated by the low rate of second attacks. This rate is usually cited as about 4 per cent, but it is likely that the figure is too high, since it is probable that erroneous diagnoses either of the first or of the second illness have often been recorded Contrary to common belief, when a single parotid is attacked the immunity which ensues would appear on the basis of the available experimental data to be as solid and persistent as when both glands are involved Infection of any organ, even in the absence of parotitis, probably induces the same high order of resistance. Finally, as already noted, there is evidence which shows that clinically inapparent infections, as revealed by the complement-fixation test (Maris et al, 1946) and the skin test for hypersensitivity (Enders et al, 1946a), confer immunity as effectively as does an overt attack. That the active immunity induced by infection can be passively transferred from mother to offspring via the placenta is strongly suggested by the fact that mumps in children under 6 or even 9 months of age is very rare. Furthermore, experiments have shown that complement-fixation and hemagglutination-inhibition antibodies are demonstrable in the cord blood and the venous blood of newborns when present in the mother These antibodies cannot be detected in the blood of most infants 40 to 60 days after birth (Florman and Karelitz, 1953).

A reasonable index of an individual's immunity can be obtained by a determination of his hypersensitivity to skin test antigen, or the level of his complement-fixing, antihemagglutinating or neutralizing antibodies. Because they are easily performed, complement-fixation or skin tests have most often been employed for this purpose. For a review of immunity in mumps see Enders (1946) and Enders and Habel (1956).

DIAGNOSIS

Mumps parotitis can usually be diagnosed with fair accuracy, particularly under epidemic conditions, on the basis of clinical criteria alone The diagnosis of sporadic cases is at times difficult, since a variety of other agents may produce an enlargement of the parotid Thus, it is sometimes necessary to differentiate mumps from suppurative parotitis, enlargements due to foreign bodies in the salivary ducts, neoplasms, Mikulicz's disease, uveoparotid fever and other rare conditions In cases where salivary gland involvement is minimal or absent and in which the virus has attacked other organs, it is frequently impossible to make a conclusive diagnosis on the basis of clinical findings alone. This is especially true in aseptic lymphocytic meningo-encephalitis—a syndrome caused by several viruses and other agents as yet unknown However, it is possible to obtain serologic evidence of any type of infection caused by mumps virus. This can be accomplished (1) by demonstrating the appearance of or increase in antibody capable of fixing complement in the presence of mumps antigen (Enders et al., 1945) and (2) by the demonstration of the appearance or increase of a specific factor, antihemagglutinin (Levens and Enders, 1945; Robbins et al, 1949), in the blood serum which inhibits the agglutination of chicken or human erythrocytes by mumps antigen These procedures have now been studied fairly extensively as diagnostic tools Because of its greater simplicity, the test for antihemagglutinin is to be recommended as routine Antigens for the complement-fixation test may be obtained in the form of a suspension of tissue from an infected parotid gland (monkey), the infected allantoic fluid of the embryonated egg, or the supernatant nutrient fluid of infected tissue cultures (Weller and Enders, 1948; Utz et al, 1957). Material from the infected parotid glands of monkeys is not a satisfactory antigen in hemagglutination-inhibition tests

As with most serologic tests, a definite diagnosis can usually be made only when a significant rise in antibody titer is demonstrated by examining 2 specimens of serum taken at appropriate intervals following the onset of the disease. Complement-fixing anti-

body against mumps virus develops rapidly in most patients so that by 1 week after the first clinical signs this substance has emerged in a majority. By the end of the 3rd week, in all cases which have been studied, antibody has been demonstrated. In many persons the antibody may persist in the circulating blood for years, although in a concentration lower than those reached during convalescence. In cases where the first specimen of serum has not been obtained sufficiently early to permit the demonstration of a rise in titer, the finding of titers exceeding 1:64 (initial serum dilution) can be interpreted as suggestive of a recent infection. By testing a single specimen of serum taken shortly after onset of symptoms for complement-fixing antibodies against the "S" and the "V" antigens, an early presumptive diagnosis can sometimes be made; since, as Henle et al (1948a) have shown, early in the disease the level of antibody reacting with "S" antigen is frequently higher than that of antibody reacting with "V" antigen. The antihemagglutinin compared with complement-fixing antibody tends to persist for a longer time at a higher titer. It should be noted that the skin test is of little or no value in diagnosis, since dermal hypersensitivity develops at widely varying intervals following the onset of mumps. Indeed, it is best not to do a skin test for diagnosis, because production of complement-fixing antibody may be stimulated by this procedure in persons who are not suffering from the disease.

Since all strains of mumps virus so far examined appear to belong to a single antigenic type, the demonstration of mumps antibody by any of the technics mentioned above may be taken, with considerable assurance, as evidence of previous infection with this agent. However, one should bear in mind that following infection with mumps virus certain persons develop antibodies which react with Newcastle disease virus of fowls (NDV). In this connection the antigenic cross relationships with influenza D (Sendai) and the Croup-Associated Viruses should also be recalled.

Diagnosis can also be confirmed by recovery of the etiologic agent, for which tissue culture is at the present time the method of choice. However, isolation procedures are usually more laborious than tests for antibodies which are employed as routine in the laboratory diagnosis of mumps. Mumps virus has been recovered in monkey-kidney-cell cultures from saliva, mouth swabs, urine and cerebrospinal fluid. In one study (Utz et al., 1957), 76 per cent of all specimens collected during the first 5 days of illness contained virus, and urine passed as late as the 13th day yielded the agent.

TREATMENT

The treatment of simple parotitis is symptomatic. In severe orchitis, recourse is sometimes had to surgical procedures for reducing the pressure caused by edema. In encephalitis, if the headache is severe, lumbar drainage may afford marked relief. There are no particular procedures employed in the treatment of the other so-called complications of mumps (Wesselhoeft, 1941). Specific therapy, consisting of the administration of various materials derived from human blood, has been attempted in the case of orchitis and meningitis. Most of the efforts have centered upon the prevention and the treatment of orchitis, the materials have been administered before the onset of orchitis but after swelling of the parotid had appeared as well as during the acute stage of orchitic inflammation. They have consisted of whole blood from recent convalescents, convalescent serum, and concentrates of globulin either from pooled normal adult plasma or from pooled convalescent sera. Results obtained in a limited number of patients in which the treatment of established orchitis or meningitis has been attempted have been equivocal, and indeed it might be anticipated that a procedure of this sort would not prove to be efficacious once the virus had caused cellular injury. On the other hand, there are limited data suggesting that concentrated gamma globulin prepared from the plasma of persons recently convalescent from mumps is of some value in preventing the development of orchitis if given after the onset of parotitis. However, concentrated normal gamma globulin has proved to be of no value under these circumstances (Gellis et al., 1945).

Several steroid hormones have been used in attempts to prevent or treat mumps orchitis.

Their value is not established, although cortisone may be effective as an analgesic (Smith and Bishir, 1958).

EPIDEMIOLOGY

Mumps is not confined to any area or climate but is world-wide in its distribution. In settled populations, it occurs as an endemic disease throughout the entire year Periodically, however, an increase in the incidence is recorded, usually during the winter and early spring months Although there is a seasonal increase at this time, which may or may not reach epidemic proportions, it is especially marked at intervals of about 7 or 8 years when severe epidemics may be observed. Both sexes are equally susceptible Although predominantly a disease of childhood, adults who have escaped infection as children are often attacked Although among the commonest of infections, a positive history of mumps is obtained less frequently among adults than is the case with certain other diseases of childhood, such as measles (mumps about 60%: measles about 90%) The frequency of inapparent infections in mumps and their rarity in measles would appear to account largely for the difference noted. The only known reservoir of infection is man. Transmission of the virus apparently takes place through direct contact, air-suspended droplets, or fomites contaminated with saliva The recent demonstration of mumps virus in human urine raises the possibility that this is a source of natural infection The exact period during which a patient may be able to transmit the disease has not been determined. There is evidence based on the isolation of virus from naturally and experimentally infected subjects that the period of infectivity may extend from 6 days before to 9 or more days after the appearance of glandular enlargement. Since the virus has been demonstrated in infected individuals who have no salivary gland enlargement, it is probable that they also are able to transmit the disease (Henle et al., 1948b; Kilham, 1949). For reviews of the epidemiology of mumps see the papers by Gordon and Heeren (1940) and Gordon and Kilham (1949)

CONTROL MEASURES

Attempts have been made to prevent the development of mumps (1) by passive immunization through the use of certain of the products mentioned for specific therapy and (2) by active immunization through the injection of inactivated or attenuated mumps virus. Most observers, who have used unconcentrated serum derived from those recently convalescent, have believed that it is of value as a temporary prophylactic measure, provided that it is administered in doses of from 5 to 20 cc. within the first few days following exposure. There is general agreement that any passive immunity so conferred is of short duration, i e., probably 2 or 3 weeks. However, a critical analysis of the available data leaves some doubt as to whether the procedure is sufficiently dependable to be of value. Experimental studies would suggest that these data have been interpreted too optimistically. Thus unpublished data (Janeway and Enders) indicate that very large doses of convalescent sera (200 ml.) might fail to prevent the disease Moreover, the concentration of virus neutralizing antibodies in convalescent sera appears to be relatively low as compared with certain other viral diseases, such as measles

During the last few years work has been undertaken on the development of a practicable method of inducing active immunity. The immunizing effect in monkeys and in human beings of virus present in emlusions of infected parotid glands from monkeys and inactivated by formalin has been studied. Any resistance so induced was challenged by inoculation of virulent virus; the vaccine prevented the development of typical infection in from 50 to 60 per cent of those who received it. Although falling short of an ideal prophylactic agent, formalinized virus has thus been shown to be capable of preventing mumps in certain persons under very severe conditions of exposure (Stokes et al., 1946) Following the development of the technic for cultivating the virus in embryonated eggs; a further step toward a practicable vaccine was taken, since this made available unlimited quantities of material containing the virus Egg virus inactivated by ether or ultraviolet light protected monkeys against experimental infection (Habel, 1946). Experiments on the protective effect of such vaccines in man have shown that the frequency of mumps among control groups exposed to the disease was 3 times that among the vaccinated (Habel,

1951a, 1951b) Since the groups included 2,825 individuals among whom 336 cases of mumps were observed, these results appear to leave little doubt of the prophylactic value of inactivated virus as vaccine, provided that exposure occurs within 4 to 6 weeks after it is administered In 1951, Henle et al., (1951c) found that large doses (4 ml) of egg-grown virus inactivated by formalin or ultraviolet light induced formation of antibodies in all susceptible recipients When naturally exposed 9 to 12 months later, a lower incidence of disease was observed in the vaccinated as compared with a control group Recently obtained unpublished data of Henle (1958) confirm the prophylactic effect of vaccination with inactivated virus Neutralizing antibodies in 90 to 100 per cent of susceptible individuals developed after 2 subcutaneous doses of vaccine given 1 to 4 weeks apart Booster doses were required 6 to 12 months thereafter in order to maintain or increase the antibody levels Study of an outbreak in an institution in which a portion of the children had been vaccinated according to this schedule of dosage indicated that the incidence of mumps was thereby reduced from 30 per cent to 5 6 per cent However, the incidence of inapparent infections in vaccinated and nonvaccinated children was similar The value of vaccination after exposure is unknown, although neutralizing antibodies may appear as soon as 1 week after administration of the first dose

In addition to investigations on the use of inactivated virus as a vaccine, studies on the effect of administering virus attenuated by repeated passage through the embryonated egg have been reported It has been shown that after such treatment the virus loses its ability to produce typical parotitis in the monkey and, with rare exceptions, in man also Such attenuated but active material renders the monkey immune to reinfection with highly virulent virus, and, on the basis of limited data, human beings as well (Enders et al, 1946b, Henle et al, 1951b) In the work just mentioned, the attenuated virus was not inoculated parenterally but introduced either via Stensen's duct or sprayed into the oral cavity Attenuated virus given in this way has been shown to stimulate antibody formation in man, although the concentrations attained did not exceed those recorded in sera of persons receiving inactivated virus Results of experiments in human beings (Henle et al, 1951b) in which high concentrations of attenuated virus were sprayed into the mouth show that up to 93 per cent of the treated individuals responded by the formation of complement-fixing antibodies A few of the children were exposed 3 months after immunization to virulent material None developed mumps These findings encourage further investigation of the method On the basis of general knowledge of immunity in virus diseases, it would be anticipated that the resistance established by a virus strain in which suitable reduction of virulence had been achieved would be more effective and more durable than that resulting from vaccination with inactivated material For detailed treatment of the various aspects of specific prophylaxis, the following references may be consulted Wesselhoeft (1940); Enders (1946), Gellis et al (1945), Lyday (1941), Stokes et al (1946), Enders et al (1946a), Gordon and Kilham (1949)

As previously noted, the available data indicate that a patient may transfer the infection to a susceptible person during a period which extends approximately from 6 days before to 9 days after onset of symptoms (Henle et al, 1948b, Gordon and Kilham, 1949) Although some workers may not entirely approve of it, the standard method of control as now recommended consists in the isolation of a patient until all swelling of affected glands has subsided Recent advances in the knowledge of the duration of infectivity may lead to a modification of this recommendation.

Infectious Mononucleosis

(SYNONYMS Glandular Fever, *Drusenfieber*, Monocytic Angina, Acute Mononucleosis)

INTRODUCTION

Infectious mononucleosis is an acute or subacute disease of young people, usually characterized by irregular fever, sore throat, lymph node enlargement, abnormal liver function occasionally with jaundice, a characteristic blood picture, and the presence of a heterophil antibody in the serum Although the etiology is unknown, it has long been suspected of being a virus disease

HISTORY

The term *glandular fever* was introduced by Pfeiffer in 1889, although there is some question today as to whether the clinical picture which Pfeiffer had in mind is identical with that of infectious mononucleosis In the United States such a disease was first reported by West (1896) in eastern Ohio The recognition of a monocytosis (or lymphocytosis) in certain acute infections was made by Turk in 1907 and later by Burns who in reporting an epidemic of glandular fever in Baltimore in 1909 called attention to changes in the differential white blood count. The term *infectious mononucleosis* apparently began to be used about 1915 but was first employed in a definitive manner by Sprunt and Evans in 1920, who quoted various cases from the literature together with 6 of their own. A year later Tidy and Morley (1921) in England identified the glandular fever of earlier writers with infectious mononucleosis. And in the United States, Longcope, Downey and McKinley added much to our present knowledge of the clinical picture In 1932 it was found that patients ill with this disease develop antibodies against sheep erythrocytes in a titer often considerably above normal (Paul and Bunnell, 1932). This finding subsequently proved to be useful in diagnosis During the 1940's it became evident that acute hepatitis is a far more common part of the clinical picture than had been suspected previously.

CLINICAL PICTURE

The incubation period is thought to be from 4 to 10 days in duration, although Hoagland (1955) believes it to be much longer The average clinical course lasts from 4 to 20 days or longer, with considerable irregularity as to type and duration. Prominent signs are characterized by generalized lymph node enlargement, mononucleosis and an increased titer of sheep cell agglutinins, yet none of these may be present during the first week of the disease, when it is most desirable to obtain a diagnosis. It is of some value, therefore, to give the clinical manifestations in chronologic order.

Incipient symptoms. The onset is often insidious and marked by nonspecific features, such as fever, headache, malaise, fatigue, sore throat, swollen cervical lymph nodes accompanied by stiffness and soreness of the neck,

leukopenia, chilly sensations and occasionally cough. The temperature curve at this early stage is one which may exhibit steplike increases with rather wide swings. Occasionally, early in its course, the fever may reach high peaks of 104° or 105° F. On the other hand, the temperature curve may be that of sustained fever at somewhat lower levels. In spite of this high fever in the evening, the temperature is often down on the following morning, so that for the first few days of illness the patient may get up and go to school or to work as usual—a fact which often makes it difficult for the physician to decide whether or not he is dealing with someone who is really sick. It may not be until the end of the first week that the diagnosis becomes evident. By this time the nodes may be sufficiently large or tender to attract attention, the blood picture begins to become diagnostic, and about this time the sheep cell agglutinins may have risen to significant titers.

Mid-stage Signs and Symptoms. It is in the second week of illness that signs and symptoms of the full-blown disease usually present themselves. Swelling of cervical lymph nodes and generalized glandular enlargement usually has been recorded in about 50 or 60 per cent of cases, respectively. A characteristic feature of these nodes at this stage is that they are tender. The spleen is enlarged in about 50 per cent of patients. A sore, red and moderately inflamed throat is common. In many of the patients the buccal cavity is also involved with stomatitis, often accompanied by patches on the tonsils and the pharynx where lesions due to Vincent's organisms are often demonstrable. Eye signs are not infrequent, and these include conjunctivitis, pain in or back of the eyes, photophobia and, later, swollen eyelids.

A rash occurs in about 10 to 15 per cent of patients. This eruption is diffuse or blotchy, generally limited to the trunk, and frequently described as morbilliform. It is often difficult to determine whether or not it is a drug rash. It may be preceded or accompanied by an enanthem consisting of petechiae on the soft palate.

Jaundice and Hepatitis. Jaundice is another manifestation present in the first or the second week of the disease, seen in about 5 per cent or less of patients, and is the overt manifestation of hepatitis which is almost universal in this disease. Indeed, liver function tests including serum transaminase determinations may reveal abnormalities in as high as 90 per cent of infectious mononucleosis patients (Cohn and Lidman, 1946; Evans, 1948; Watson et al., 1951, Rennie and Wroblewski, 1957). The suggestion has even been made that such tests might be of considerable diagnostic aid in questionable cases of infectious mononucleosis.

Involvement of the central nervous system, first described by Johansen (1931), now constitutes an uncommon but very important consideration. Such manifestations, which have been reviewed by Bernstein and Wolfe (1950), are said to occur in 1 per cent of the proved cases. The clinical picture has been that of acute serous meningitis, with or without encephalitis and neuritis. Signs and symptoms of such involvement are headache, disturbances of consciousness, nuchal rigidity, convulsions, cranial nerve palsy, motor and sensory disturbances. A peculiar feature of this "complication" is the irregularity in time in which these symptoms appear. They may come on from 1 to 3 weeks after onset of the disease, but, on the other hand, they may be the initial indication of the infection.

Cardiac involvement is as a rule subclinical and benign, although the existence of myocarditis in infectious mononucleosis has been confirmed at autopsy, and acute pericarditis has also been described. Clinically, myocarditis can be demonstrated now by transient and nonspecific electrocardiographic alterations.

Renal involvement also occurs, as is evident from the occasional finding of gross or microscopic hematuria, proteinuria and casts. Thrombocytopenic purpura, acute hemolytic anemia, and hemoglobinuria have been observed occasionally. In one fatal case there were small hemorrhages in the spinal cord, mainly in the posterior horns of the gray matter. Rarely x-ray studies in some patients have revealed pulmonary infiltrations indistinguishable from those of primary atypical pneumonia.

Late Stages, Subacute or Chronic Forms. Usually, the acute disease lasts from 10 days to 2 weeks with symptoms subsiding within 3 weeks, although lymphocytosis may

Infectious Mononucleosis

(SYNONYMS. Glandular Fever, *Drusenfieber*, Monocytic Angina, Acute Mononucleosis)

INTRODUCTION

Infectious mononucleosis is an acute or subacute disease of young people, usually characterized by irregular fever, sore throat, lymph node enlargement, abnormal liver function occasionally with jaundice, a characteristic blood picture, and the presence of a heterophil antibody in the serum. Although the etiology is unknown, it has long been suspected of being a virus disease

HISTORY

The term *glandular fever* was introduced by Pfeiffer in 1889, although there is some question today as to whether the clinical picture which Pfeiffer had in mind is identical with that of infectious mononucleosis In the United States such a disease was first reported by West (1896) in eastern Ohio The recognition of a monocytosis (or lymphocytosis) in certain acute infections was made by Turk in 1907 and later by Burns who in reporting an epidemic of glandular fever in Baltimore in 1909 called attention to changes in the differential white blood count. The term *infectious mononucleosis* apparently began to be used about 1915 but was first employed in a definitive manner by Sprunt and Evans in 1920, who quoted various cases from the literature together with 6 of their own A year later Tidy and Morley (1921) in England identified the glandular fever of earlier writers with infectious mononucleosis. And in the United States, Longcope, Downey and McKinley added much to our present knowledge of the clinical picture. In 1932 it was found that patients ill with this disease develop antibodies against sheep erythrocytes in a titer often considerably above normal (Paul and Bunnell, 1932) This finding subsequently proved to be useful in diagnosis. During the 1940's it became evident that acute hepatitis is a far more common part of the clinical picture than had been suspected previously

CLINICAL PICTURE

The incubation period is thought to be from 4 to 10 days in duration, although Hoagland (1955) believes it to be much longer. The average clinical course lasts from 4 to 20 days or longer, with considerable irregularity as to type and duration Prominent signs are characterized by generalized lymph node enlargement, mononucleosis and an increased titer of sheep cell agglutinins, yet none of these may be present during the first week of the disease, when it is most desirable to obtain a diagnosis. It is of some value, therefore, to give the clinical manifestations in chronologic order.

Incipient symptoms. The onset is often insidious and marked by nonspecific features, such as fever, headache, malaise, fatigue, sore throat, swollen cervical lymph nodes accompanied by stiffness and soreness of the neck,

been inoculated 16 days before with similar material from a patient with infectious mononucleosis. The volunteer later developed hematologic and serologic evidence of the disease, but had no clinical symptoms. Wising, in 1942, used 250 ml of heparinized whole blood from a patient in the acute phase of infectious mononucleosis and injected this intravenously into volunteers, one of whom developed an illness clinically suggestive of infectious mononucleosis, but with only a slight rise in sheep cell titer. Havens in 1945-46 and Evans (1947b, 1950) attempted experimental transmission in more than 40 human volunteers, aged 19 to 25 years, by using pooled human throat washings, and serum and stool preparations inoculated by oral, intranasal, intramuscular and intracutaneous routes. However, although suggestive evidence of mild infectious mononucleosis occurred in several inoculated subjects, there was insufficient evidence to term any of these transmissions truly successful.

ETIOLOGY

A number of different microbial forms, both bacterial and spirochaetal, have been suspected of being the etiologic agent of infectious mononucleosis, but as yet none has been established. The present view is that if the agent is a bacterium or a protozoan, it is a most difficult one to demonstrate. The chances are better that this disease is of viral origin, but here again this has not been demonstrated. The only known properties of this as yet unidentified agent are those which have been mentioned under other headings in this chapter, which deal with transmission experiments. To indicate that this situation needs further investigation is a gross understatement. As to modes of human transmission, the balance of circumstantial evidence suggests that the mouth is the portal of entry, and recently Hoagland (1955) has suggested that, on the basis of clinical records, infectious mononucleosis may well be transmitted by direct and intimate oral contact, which allows for moderate salivary exchange, and that an incubation period of 33 to 49 days follows such exposure. Besides the implication that the agent may be in the mouth, suggestive information has come from the experimental work of Sohier et al. (1940) and Wising (1942) that during the acute phase of the disease the agent is in the blood and the lymph nodes.

DIAGNOSIS

Owing to its extremely variable clinical manifestations, infectious mononucleosis has one or more features in common with a large number of other diseases. In this respect at least, the serologic test is a particularly useful diagnostic measure.

Differential Diagnosis. In the differentiation of infectious mononucleosis from those diseases associated with sore throat and pharyngitis one should be on the lookout for cases of *Vincent's angina, diphtheria, herpetic pharyngitis, aphthous stomatitis* and, more commonly, *acute follicular tonsillitis* with its frequently associated regional lymph node enlargement. Other conditions with lymph node enlargement, particularly enlargement of the cervical chain, include the following: *tuberculosis, Hodgkin's disease, mumps* and occasionally *syphilis*. Certain acute diseases associated with a rash, notably *German measles* and recently described ECHO virus infections, have been confused with infectious mononucleosis. Also in this category is *serum disease* and *an untoward response to drugs*.

From the standpoint of those diseases which present a comparable blood picture, *acute lymphatic* or *monocytic leukemia* may be mistaken for infectious mononucleosis. Bone marrow biopsy may be inconclusive as may be the microscopic appearance of a lymph node removed early in the illness, although in well-established chronic lymphatic leukemia the characteristic features of an invasive process are present. Sheep cell agglutinins are not present in the leukemias.

Of considerable importance is the ease with which infectious mononucleosis may be confused with *infectious hepatitis*. Hepatitis may be present in both conditions, and during the early stages of infectious hepatitis a blood picture not unlike that seen in infectious mononucleosis is common. The serologic test is particularly valuable here, as sheep cell agglutinins do not reach diagnostic titers in infectious hepatitis.

Other diseases which may be confused with

persist for a few weeks, and the lymph nodes may remain somewhat enlarged for months. On the other hand, complete recovery may be delayed for many months. In Niederman's recent (1956) series of 166 patients, about 10 per cent had either objective or subjective symptoms beyond 3 weeks Generalized lymph node enlargement continued in 73 per cent, and splenomegaly in 47 per cent of the individuals Symptoms of malaise and anorexia persisted in some instances for several weeks, and one patient experienced generalized adenopathy and low-grade fever for a period of 12 months The syndrome included: ease of fatigue, exhaustion, aching of the legs, weakness, depression, afternoon elevation of temperature from 99.8° to 101° F, splenomegaly, low blood pressure, and the presence of infectious mononucleosis cells in the blood. This syndrome has been known to last for 4 years or even longer.

Blood Picture. Anemia is uncommon, and the *red blood count* usually remains at normal levels Rarely, however, hemolytic anemia appears as a complication There are wide variations in the *total white blood cell* count, but an early leukopenia is often apparent (i e., between the 4th and the 10th days). The low counts range around 4,500 per cu mm, an extreme low being about 2,000 Leukopenia is then followed by a moderate leukocytosis, averaging about 10,000; it may range as high as 50,000 white blood cells or even greater The leukopenia is a *granulocytopenia*, and actually the granulocytes remain more or less reduced in number for almost 2 weeks. The subsequent increase in total white cells beginning around the 10th to the 17th days is largely due to an increase of lymphoid cells The nature of these characteristic, mononuclear (infectious mononucleosis) cells has been the basis of much discussion It is usually thought that most of them are altered or pathologic lymphocytes. The abnormal lymphocyte is variable in size and staining qualities, although it is generally large with a light-staining cytoplasm A small proportion of these cells, as well as the normal small lymphocytes, may show fenestration in the nucleus

In general, the blood picture in this disease is an exaggeration of the response familiar in a variety of acute febrile diseases of virus origin, particularly reminiscent of that seen in infectious hepatitis.

PATHOLOGIC PICTURE

Although it is suspected that infectious mononucleosis is a respiratory infection, with the mouth as the portal of entry, this has not yet been proved It would seem, in any event, that it becomes a *systemic infection*.

Biopsy Material. Custer and Smith (1948) have studied material from over 100 lymph node biopsies. In the latter series the lymph nodes displayed a variety of appearances ranging from a scattering of abnormal lymphocytes, to the distortion of architectural structure as a result of lymphocytic or reticuloendothelial hyperplasia. Serial liver biopsies have been used to follow the diffuse hepatitis which has a histologic picture close to but not identical with that of infectious hepatitis.

Autopsy Material. Deaths are rare, therefore the amount of this material is not large. In Custer and Smith's autopsy series of 9 cases the *gross* pathologic changes were almost exclusively confined to enlargement of lymphoid tissues, especially the spleen Nasopharyngeal lymphoid hyperplasia was constant Histologic observations revealed more or less generalized lesions widespread throughout the body and consisting of focal or perivascular aggregates of normal and abnormal lymphocytes In some cases reticuloendothelial hyperplasia was so marked as to suggest a lymphoma.

EXPERIMENTAL INFECTION; HOST RANGE

Experimental transmission, except for a few suggestive attempts in man, has not been achieved or confirmed. Repeated attempts to transmit this disease to small laboratory animals and primates, including chimpanzees, have been unsuccessful in almost every instance Such attempts have been made by Bang (1943), Julianelle et al. (1944) and others, in addition, inoculations of embryonated eggs and more recently a variety of tissue culture systems have been tried, all unsuccessfully.

The work in man deserves more than passing mention. In 1940, Sohier et al. inoculated a human volunteer intramuscularly with 6 ml of whole blood from a monkey which had

this test is enhanced when sequential tests are used.

The presence of a positive Kahn, Wassermann or Mazzini test has been noted in about 5 per cent of the cases. Usually this has been seen in those cases which have had high titers of sheep cell agglutinins and, as the agglutinins have regressed, so also have the titers of the Wassermann and the Kahn tests

TREATMENT

Acute Stage. Patients may be cared for by a general practitioner and seldom require the supervision of specialists Hospitalization is not an essential part of the therapy, but many patients with this disease are sick enough to require hospital care Isolation technic is not necessarily recommended Therapy consists mainly in caring symptomatically for a patient who may have high fever (105° F), severe stomatitis, sore throat and painful swollen lymph nodes, particularly in the neck Always there is the danger of rupture of the spleen Bed rest, adequate fluid intake and light diet as for any acute infection are indicated

The care of the mouth and irrigation of the throat with warm saline solutions are particularly indicated If stomatitis is present, the use of potassium perborate, or in some instances potassium chlorate solution (a saturated solution diluted 50% in water) as a mouth wash not more than twice a day, is helpful

It is the physician's duty to be on the alert for complications, such as jaundice, or rarely, meningo-encephalitis and hemolytic anemia In the cases with hepatitis the same general principles of therapy used in infectious hepatitis should be considered There is no particular reason to reduce the amount of fat in the diet after the patient is on the mend

Although the disease is rarely fatal, one should understand that fatalities are not unknown and when they occur are often the result of rupture of the spleen This may result from minimal trauma Therefore, repeated abdominal palpitation and exertion on the part of the patient while the spleen is enlarged should be avoided Exploratory laparotomy is indicated for severe abdominal pain in this disease, for it may be a lifesaving procedure

Chlortetracycline has been suggested, but controlled studies do not indicate that this antibiotic is effective Sulfonamide drugs are

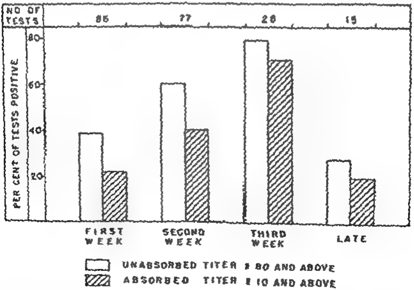

FIG 119 Heterophil antibody determinations in a series of 166 cases of infectious mononucleosis listed according to various stages of the disease (Niederman, J C, 1956, Yale J Biol & Med 28, 629)

infectious mononucleosis include. *acute appendicitis, trichinosis, acute rheumatic fever, undulant fever* and *acute infections of the central nervous system*, particularly the group known as *aseptic meningitis*

Acquired *toxoplasmosis*, as demonstrated by Siim (1951) in Denmark and Skipper et al (1954) in England, produces in a certain number of young adult patients, a febrile illness associated with lymphadenopathy. The diagnosis of toxoplasmosis is made by special serologic means.

It is quite possible that a clinical picture resembling that of infectious mononucleosis, as we know it today, embraces a number of different entities, some of them ill-defined, including a disease described by Blake et al. (1942). In none of these, however, is the infectious mononucleosis (heterophil) antibody present

Another condition to be considered here, which is usually but not always confined to children, is that of *acute infectious lymphocytosis*, described by Smith (1944) and Barnes et al (1949).

Perhaps the most valuable of laboratory tests are the total white and differential blood counts to which reference has already been made. Recognition of a lymphocytosis and the predominating type of mononuclear cells which have been designated as characteristic of infectious mononucleosis is of primary importance However, the mere presence of these cells, *in the absence of other typical signs*, is not diagnostic. Randolph and Hettig (1945) have reported the fairly frequent occurrence of these infectious mononuclear cells in the peripheral blood of individuals with a variety of allergic conditions.

Serologic Diagnosis. The sheep cell or heterophil agglutination test for the diagnosis of infectious mononucleosis is a *nonspecific* [illegible] which [illegible] nce of [illegible] he infectious mononucleosis antibody, which differs from other antibodies found in human [illegible] these [illegible] differentiation between these various antibodies is based on the fact that sheep cell agglutinins in infectious mononucleosis can be completely absorbed by beef erythrocytes but are not reduced significantly by absorption with guinea pig kidney. In serum sickness, sheep cell agglutinins can be completely absorbed by both guinea pig kidney and beef erythrocytes. Sheep cell agglutinins in normal serum are not ordinarily absorbed by beef cells but can be completely or almost completely absorbed by guinea pig kidney.

For the development of technics useful in carrying out this test the reader is referred to Stuart et al. (1936), Davidsohn (1937), Paul (1949); and, for a qualitative, rapid micromethod to Evans (1947a). There is some disagreement concerning the arbitrary figure which has been selected as representing a diagnostic titer of sheep cell agglutinins in infectious mononucleosis serum This stems from the fact that variable technics have been used When the procedure recommended by the author in 1949 is followed, titers which range from 1:10 to 1 40 should be considered negative, from 1:80 to 1:160 as suspicious; and those above 1:160 may be referred to as *positive. The best criterion in the early stages* is that of a rising titer. The values quoted above apply to an unabsorbed titer, but it should be recognized that any completely absorbed titer with guinea pig kidney of 1·10 or greater is serologically valid for the diagnosis of infectious mononucleosis

Although useful as a diagnostic test, the heterophil antibody test is not always positive in infectious mononucleosis; In fact, figures on this point differ widely in different series There are also many examples of false positives, Zarafonetis et al. (1953). The degree to which *positive titers*, obtained according to criteria just described, were recorded in various weeks of the disease in a series of 166 cases is illustrated in Figure 119. These data are based on the results of 206 serologic tests It will be seen that during the first week of illness, only 38 per cent of the cases had significantly positive titers, but that this increased to 60 per cent during the 2nd week of the disease. A precipitous decline in the heterophil antibody titers then follows in the 4th and subsequent weeks, and from this it is evident that high titers are apt to be transient and short-lived. It is also apparent from these data that the diagnostic value of

lower peak in the fall, perhaps associated with the date of the opening of schools or colleges In other series, no seasonal trend has been observed

Little is known about *immunity* in this disease, although it is strongly suspected that one attack gives lasting immunity. Evidence for this rests primarily upon the age distribution of the cases, which [illegible] seen in individuals over 35 is that the majority of them have already had it *On the other hand, there* are not infrequent claims of second attacks separated by several years It is quite probable that they may occur, although carefully *documented second attacks are not often seen.*

In general, therefore, one can assume that this disease is spread by some form of person-to-person association, and, either that it is not due to a highly infectious agent, or that a special type of intimate contact is necessary It would also seem that the degree of resistance (immunity) in most adult populations is moderately high

TABLE 31. PERCENTILE AGE DISTRIBUTION BY 5-YEAR AGE-GROUPS OF 2 SERIES OF CASES (1 EUROPEAN AND 1 AMERICAN) OF INFECTIOUS MONONUCLEOSIS

AUTHOR	AREA	NO IN SERIES	AGE GROUPS (IN YEARS)							
			0-5	6-10	11-15	16-20	21-25	26-30	31-35	36+
Thomsen (1942)	Denmark	545	5.5	9.9	10.5	41.0	24.9	5.5	2.5	0.4
Niederman (1956)	New Haven, Conn., USA	166	12.0	4.2	2.4	18.6	38.3	13.2	4.2	6.6

of no value and may be harmful. Steroid therapy is beneficial in selected patients with severe toxic symptoms, particularly of the anginose type.

Subacute Stage. Occasionally, cases of infectious mononucleosis may be extremely protracted, lasting weeks or even months For this reason a guarded convalescence is part of the therapeutic regimen Cases have been reported which have recurred after surgery, the suggestion being that the operation has *precipitated a relapse*

Prophylaxis. There are no measures to be recommended which are known to control the spread of this disease Although isolation technics have been used in some countries for the care of acutely ill patients with this disease and may be theoretically advisable, they are not usually practiced Nevertheless, disinfection of nose and throat discharges would seem to be indicated in the general care of patients with the acute disease

The use of gamma globulin as a prophylactic measure has not been established.

EPIDEMIOLOGY

Increasing in recognition, infectious mononucleosis is now common in many parts of the world, notably the United States, England and Europe A report from the British Royal Navy (Rugg-Gunn, 1954) ranks it second in frequency to rubella, if the common cold and influenza are excluded However, there has been a significant lack of the occurrence of recognizable epidemics of bona fide examples of the disease. Apparently this [illegible] ted easily, for although

Robinton, 1950, Hoagland, 1952). Cross-infections in an open hospital ward have also been notable by their absence. Nevertheless, occasional epidemics have been reported since the 1890's in boarding schools, colleges, foundling homes, hospital wards, prisons and small communities.

As the age distribution of any disease can often be an indication of the most or *least* susceptible segment of the population, or that segment which is more or less heavily exposed, this deserves some attention. In the *majority of series there is an increase in frequency of cases in the age group of 15 to 25 with a concentration of cases in the age group 16 to 20 in one European series, and in the age group 21 to 25 in a series from* the United States (see Table 31). This table demonstrates a rather unusual age distribution for an infectious disease. A number of reports stress the frequency of infectious mononucleosis in childhood, but this has not been the experience of all general hospitals It is possible that, as in the case of infectious hepatitis, infectious mononucleosis may occur far more commonly in childhood than is suspected, but that it is so mild in childhood *that it escapes recognition* As to the *sex distribution,* the disease is more common in males than in females, and from the occupational standpoint it is prone to appear among young people who live in institutions, colleges, or military establishments. Among [illegible] dents than about the United States

those who work in hospitals Indeed, the frequency with which infectious mononucleosis has attacked nurses, interns and medical students is proverbial.

As to *seasonal trends,* opinions differ on this point. In some areas a rise of incidence in the spring has been reported with another

lower peak in the fall, perhaps associated with the date of the opening of schools or colleges In other series, no seasonal trend has been observed

Little is known about *immunity* in this disease, although it is strongly suspected that one attack gives lasting immunity Evidence for this rests primarily upon the age distribution of the cases, which indicates that it is essentially a disease of children and young adults, one could merely infer by deduction that the reason it is seldom seen in individuals over 35 is that the majority of them have already had it. On the other hand, there are not infrequent claims of second attacks separated by several years It is quite probable that they may occur, although carefully documented second attacks are not often seen

In general, therefore, one can assume that this disease is spread by some form of person-to-person association, and, either that it is not due to a highly infectious agent, or that a special type of intimate contact is necessary It would also seem that the degree of resistance (immunity) in most adult populations is moderately high

The Typhus Fevers

The typhus fevers comprise the first group among the infections which are referred to as the rickettsial diseases of man These infections have several features in common The causative micro-organisms, called rickettsiae, can be observed readily in the light microscope as pleomorphic coccobacillary forms, but they multiply only within certain cells of susceptible species For these reasons the rickettsiae are classified as a family between the viruses and the bacteria A distinctive characteristic of the rickettsiae is their occurrence in various arthropods under natural conditions The rickettsial diseases are divided into 4 main groups on the basis of their clinical features, their epidemiologic aspects and their immunologic characteristics

1 Typhus group (discussed in this chapter)
   A Epidemic (louse-borne) typhus
   B Brill-Zinsser disease (recrudescent typhus)
   C Murine (flea-borne) typhus
2 Spotted-fever group (Chap 43)
3 Scrub typhus (Tsutsugamushi disease) (Chap 44)
4 Q fever (Chap 45)

Trench fever, presumed to be rickettsial in etiology (Chap 46)

EPIDEMIC LOUSE-BORNE TYPHUS

(SYNONYMS Jail fever, war fever, famine fever, morbus hungaricus, *typhus historique, typhus exanthematique, dermotypho, tabardillo, typhus exantematico, Fleckfieber*)

INTRODUCTION

Typhus fever is an acute infectious disease characterized by sustained high fever, severe headache, generalized macular or maculopapular rash, and termination by rapid lysis in 14 to 18 days The over-all case-fatality rate in epidemics is about 20 per cent The etiologic agent was named *Rickettsia prowazeki* in honor of two investigators, Dr Howard Taylor Ricketts, an American, and Dr S von Prowazek, an Austrian, who died of typhus fever in the course of their studies of its etiology (da Rocha-Lima, 1916)

HISTORY

Typhus fever has probably afflicted mankind since ancient times The description by Fracastorius in 1546 is the earliest medical record which is sufficiently clear to identify typhus fever as a separate entity Arguments have been advanced (MacArthur, 1954) that the great epidemic in Athens in 430 B C must have been typhus, but the account leaves some doubt despite the vivid description given by Thucydides

The word "typhus" is derived from the Greek, *typhos*, meaning smoky or hazy Although the term had been used by Hippocrates to depict a "confused state of intellect with a tendency to stupor," it was not actually applied to typhus fever until 1760 when Sauvages selected it to describe the mental

CLINICAL PICTURE

The incubation period usually is from 10 to 14 days, but it may be shorter if the infecting dose is unusually large. Prodromal symptoms occur infrequently; if present, they are headache, lassitude and weakness, sometimes accompanied by slight fever. Onset is usually abrupt, and patients are frequently able to state the exact hour at which they noted the beginning of their illness The first symptoms are malaise, chilly sensations, headache, weakness, generalized aches and pains During the first 2 or 3 days the temperature may fluctuate from normal to 39° C, but after the third day it attains a level of 39° to 41° C where it remains until death or recovery of the patient (Fig 120).

There may be one or more shaking chills early in the first week Headache increases in severity and may be generalized or most severe in the frontal region, it is one of the most constant features of typhus fever, and efforts to diminish its intensity usually fail Patients tend to cough in the first week of disease without raising much, if any, sputum Vomiting occurs infrequently with the onset of the disease and is rare after the third day, except when azotemia develops Constipation is far commoner than is diarrhea Patients may appear to be deaf, and they often complain of ringing in the ears or vertigo Pains in the muscles of the back and the legs may be very troublesome The appearance of a generalized eruption, usually between the 4th and the 7th days of the disease, is an important feature Preceding the rash in some instances, there may be a transient blotchy erythema or a marbled appearance of the skin, sometimes referred to as subcuticular mottling The characteristic rash is first apparent on the trunk, spreading in the course of 1 or 2 days over the entire body except the face, the palms and the soles, which are involved only in gravely ill patients Lesions have been recognized on the soft palate in rare instances At first the skin lesions are macules or maculopapules about 2 to 4 mm in diameter, pinkish to bright red in color, with rather indefinite borders Slight pressure causes them to fade completely This eruption has been described as a "mulberry rash" (Fig 121)

The rash may be absent throughout the

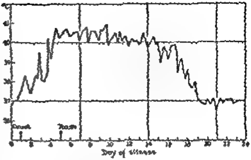

FIG 120. Temperature curve, epidemic typhus fever

disease in perhaps 10 per cent of light-skinned persons, lesions are even more difficult to detect in dark-skinned persons In the first few days, the pulse rate may not be quite so high as the temperature would warrant, but toward the end of the first week and for the remainder of the disease the pulse rate is rapid in proportion to the temperature The blood pressure is usually low, and there may be brief periods of severe hypotension The respiratory rate is quite often increased out of proportion to any findings in the chest Toward the end of the first week, patients exhibit varying degrees of photophobia and suffusion of the conjunctivae The face is often flushed and sometimes assumes a dusky appearance Some observers have commented on the presence of facial edema in certain patients Delirium may appear, but it is more common to observe only mental dullness or slight stupor at this stage The urine frequently is reduced in amount, and the specific gravity is elevated Sometimes there may be inability to void or incontinence of urine and feces, although these usually do not occur before the 2nd or 3rd week

In the 2nd week of illness, the skin lesions become darker in color, assuming a reddish to reddish-purple hue, pressure no longer causes them to fade In mild cases the rash may last for 2 or 3 days and then disappear In moderately or severely ill patients, the lesions are usually visible until the end of the febrile period In many of the severe cases the rash becomes petechial or even frankly hemorrhagic Confluence of the rash has been noted in very severely ill patients In general, there

state of patients suffering from the disease It should be emphasized that *typhus* and *typhoid* fevers were frequently confused until 1837 when W. W. Gerhard in Philadelphia called attention to the important clinical and pathologic differences between the two diseases Confusion in terminology persists even now, since *typhoid fever* is called *typhus abdominalis* in some parts of Europe.

Typhus fever always has been intimately associated with wars, famines and human misfortunes Its effect on the outcome of battles has often been decisive The earliest military chronicle implicating typhus is that which describes the siege of Granada in 1489, there were 17,000 deaths from typhus in the Spanish Army, almost [illegible] times the number killed in combat with the Moors Perhaps typhus was brought to Spain by the Spanish soldiers who had fought against the Turks in Cyprus. Soon thereafter the disease broke out in Italy where Fracastorius had occasion to study its characteristics In 1528, the French Army besieging Naples was at the point of decisive victory over the forces of Charles V, a victory which would have had enormous effects on the subsequent developments in Europe. But then " [illegible] typhus made its political debut—by one of the most far-reaching and profoundly effective strokes of its entire career [illegible]." (Zinsser, 1935) With great rapidity it struck down 30,000 soldiers in the camps of the French, and the remnants of the army were forced to withdraw

The Balkan campaigns in the 16th century contributed greatly to the spread of typhus across Europe Large forces were assembled from various parts of Germany, Italy and France for combat with the Turks, but many of the men were stricken by typhus before they reached the battlefields The disease became known as the "morbus hungaricus," since it was disseminated throughout Europe by [illegible] first [illegible] Nev[illegible] Sab[illegible] refers to the severe epidemic in the highlands of Mexico in 1576 and 1577 during which more than 2 million Indians died. Although the records suggest that typhus fever may have existed in the New World before the arrival of the Spanish explorers, it is not possible to decide this point on present evidence.

The disaster which befell Napoleon's army of half a million men in 1812 was in part the work of typhus. During the period from 1816 to 1819, a great epidemic of typhus is said to have caused at least 700,000 cases among the 6 million inhabitants of Ireland Typhus tended to subside somewhat in the last half of the 19th century, but it reappeared again in World War I, striking Serbia severely in 1915. There were only 400 Serbian doctors, and almost all of them contracted typhus; 126 of these doctors died. The mortality in the civilian population ranged from approximately 20 per cent during the rise and decline of the epidemic, to 60 and even 70 per cent at its height. In less than 6 months more than 150,000 Serbians died of typhus (Strong et al, 1920). Between 1918 and 1922, typhus ravaged Russia; estimates place the number of cases as high as 30 million in this period and deaths as many as 3 million

During World War II typhus more than once threatened to complicate military operations The areas of North Africa in which [illegible] in Naples just as that badly overcrowded and heavily bombed city was occupied by the Allied forces. In 1944, the Yugoslavian army, engaged in bitter struggle with the Germans, was severely handicapped by the spread of typhus not only in the civilian population but in the army itself. As the Allied armies crossed Germany in 1945, typhus was encountered in many of the notorious Nazi concentration camps. Although only a very short interval elapsed between the liberation of these camps and the arrival of adequate forces to maintain discipline and control from the sanitary point of view, many of the louse-infested, typhus-infected inmates escaped into the surrounding countryside, scattering far and wide. Attempts to restrict the spread of typhus were vastly handicapped by the floods of persons who had been transplanted into Germany from occupied countries; more than a million of these "slave laborers" were freed by the Allied armies, and nearly all crowded the roads seeking to return to their own countries. Shortly after the cessation of hostilities in the Far East, Japan and Korea underwent a severe typhus epidemic of approximately 26,000 cases.

The examples cited above suffice to indicate that epidemic typhus has been one of the major epidemic diseases in the history of man It is probable that typhus fever has been exceeded only by malaria as a cause of widespread human suffering.

acter increases The parts subjected to pressure and particularly the skin over the sacrum become red and tender, and are liable to slough The pulse ■ frequent (112 to 140), small, weak, and undulating, and not unfrequently [sic] intermittent, irregular, or scarcely perceptible, the cardiac impulse and systolic sound of the heart are diminished in intensity, or absent (Murchison, 1884, pp. 122-123)

To this account a few more details may be added to complete the picture of the critical period of the illness Persistent cough with difficulty in expectoration may be accompanied by development of a patchy pulmonary consolidation, more often disclosed by roentgenograms than by physical examination *Respirations are usually rapid and somewhat shallow*. The blood pressure continues to be lower than normal and may fall below 80/50 in severe cases. *Although the myocardium is damaged, the syndrome of congestive heart failure does not appear in the acute stage of the disease Gallop rhythm often develops* in severely ill patients The spleen becomes palpable in about half the cases. Renal insufficiency of varying degree is a common occurrence Oliguria and elevated blood urea nitrogen *are nearly always features of the* clinical course of fatal cases of typhus fever. (Fig 122) Gangrene of the toes, feet, tips of fingers, *ear lobes, nose, penis, scrotum* or vulva may occur Parotitis, otitis media and furunculosis are common complications which may appear toward the end of the 2nd week of illness

In fatal cases, the terminal period is usually characterized by profound stupor which

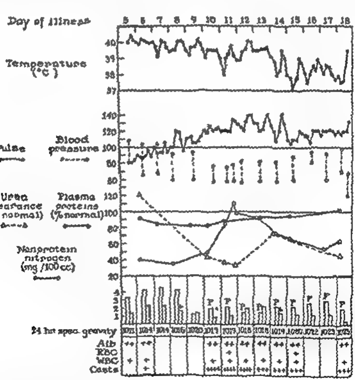

FIG 122 Graphic representation of clinical findings on a male patient, 46 years old, admitted on 5th day of disease, dying on 18th day In space on chart directly above "specific gravity," data about fluid intake and output (liters/24 hrs) are portrayed, P represents fluid given parenterally (Yeomans, A, Snyder, J C, Murray, E S, Ecke, R S, and Zarafonetis, C J D, 1945, Azotemia in typhus fever, Ann Int Med 23, 735)

FIG 121 Typical rash of typhus fever, 11th day of disease (U S A Typhus Commission)

is no residual evidence of the rash after recovery; in rare instances, however, brownish areas of pigmentation are visible for several months If a patient dies, the rash ordinarily persists after death, particularly in dependent areas.

The 2nd and 3rd weeks of illness constitute the critical period. Increasing prostration develops, and patients are unable to eat or drink without assistance. Mental dullness supervenes, and patients seem to be quite deaf. The dullness may progress to stupor or coma. The stupor may be interrupted by brief episodes of delirium in which patients become active or even violent and then lapse back into apathy. They may mutter to themselves or carry on conversations with imaginary friends. In rare instances, stiffness of the neck may develop in sufficient degree to prompt the performance of a lumbar puncture; the spinal fluid may be under slightly increased pressure but otherwise is normal Murchison gave the following account of the clinical picture of typhus in the 2nd week of the disease which is remarkable for its accuracy:

. . . the stupor and delirium alternate, the latter being most marked in the night-time. The prostration is extreme the patient lies on his back, moaning, muttering incoherently, or still and motionless, with a tendency to sink to the bottom of the bed. He is quite unable to raise himself, or even to turn on his side, is with difficulty aroused, and is utterly indifferent to surrounding objects and persons Tremors, subsultus, and picking of the bedclothes may be observed The expression is stupid and vacant; the conjunctivae are injected, the eyelids for the most part closed, and the pupils often contracted. Deafness is not uncommon. If spoken to loudly, the patient opens his eyes and stares vacantly at those about him, and when told to put

mind is far from inactive, the imagination conjures up the most frightful fancies, to which implicit belief is attached, and of which a distinct recollection may remain after recovery The teeth and lips are now covered with sordes; the tongue is hard and dry, dark brown or black, contracted into a ball, tremulous and protruded with difficulty or not at all The abdomen is flaccid, or sometimes tympanitic; the bowels are still confined, or one or two slightly relaxed motions are passed daily in bed The urine is more copious, but paler, and of low specific gravity, and is

after initiation of intensive therapy, the progress of the disease is usually arrested, and improvement occurs within 2 to 3 days, as the temperature subsides and the prostration and the mental apathy lessen The earlier that treatment is begun in the illness, the more prompt the recovery and the shorter the period of convalescence Treatment may fail if not administered before the patient has developed severe azotemia and extensive tissue damage from vascular lesions

Pathologic Picture

There are no gross findings characteristic of typhus fever at necropsy except the skin lesions Bronchopneumonia, myocardial changes and petechial hemorrhages in the subcutaneous tissues and the brain are the principal features which may be observed Rarely, symmetrical gangrene of the extremities and thrombosis of a large blood vessel may be present The microscopic pathology of typhus is quite characteristic Rickettsiae multiply inside endothelial cells lining small blood vessels Affected cells become swollen, and proliferation occurs as shown by numerous mitotic figures Thrombosis results from injury caused by rickettsial growth Accumulation of polymorphonuclear leukocytes, macrophages and lymphoid cells around such lesions in capillaries, arterioles or venules gives rise to distinctive histologic appearance sometimes referred to as Fraenkel's nodules (Fig 123) Early stages in the development of these lesions have been studied by skin biopsies (Wolbach, Todd and Palfrey, 1922) Rickettsiae can be demonstrated by careful technic in some of the endothelial cells Vascular lesions are most numerous in the skin,

Fig 123 Section of brain of patient who died of typhus fever on 13th day of disease, showing a typical typhus nodule in the medulla oblongata, note proliferative character of the lesion (×275) (Dr W B MacAllister and the U S A Typhus Commission, photograph by Dr. R M Allen)

changes to coma; some patients have other features characteristic of uremia. Cyanosis deepens and pulmonary consolidation develops to an extent readily detectable by physical examination The blood pressure may fall to a very low level Evidence of peripheral vascular collapse may be noted shortly before death. The skin becomes cold and moist with a livid appearance; the pulse becomes very faint or absent at the wrist, and death ensues. In some instances, the temperature may drop to subnormal values a few hours before death Unless the fatal termination is due to secondary bacterial infection, death from typhus per se usually occurs between the 9th and the 18th days of illness.

If a patient recovers, the fever generally subsides by rapid lysis in the 3rd week of illness, the temperature becoming normal or subnormal within 2 or 5 days. The mental state improves strikingly when the temperature begins its descent With the exception of infrequent cases of very severe encephalitis due to typhus itself, recovery of normal mental and physical capacities is remarkably rapid in convalescence Full strength and activity are regained in 2 or 3 months. An astonishing feature of the disease is the absence of serious sequelae, despite the fact that the central nervous system, the myocardium and the kidneys are dangerously involved in the acute stage.

The hemoglobin and red blood cell count decrease during the course of typhus, particularly in the 2nd and the 3rd weeks of illness when the red count may fall to 3 5 million cells per cu mm with a corresponding reduction in hemoglobin values. Return to normal levels usually is rapid In the first week of illness, the white blood cell count tends to be somewhat reduced, values range from 8,000 to 2,000 cells per cu. mm. Differential counts are interesting chiefly because of the constant absence of eosinophils during the febrile period In the 2nd and the 3rd weeks of illness, the white blood cell count may be normal or slightly elevated. In the presence of secondary bacterial complications, the leukocyte count may be considerably above normal. Practically all patients have albumin in the urine in varying amounts while fever is present. There is a tendency for the specific gravity of the urine to be high during the 1st week, possibly because of dehydration. In the 2nd and the 3rd weeks of the disease, severely ill patients may excrete only small amounts of urine of relatively low specific gravity. Diuresis has been observed at the beginning of the convalescent period in some patients. Red blood cells may occur in the urine in varying numbers, but gross hematuria is a very rare finding. However, granular casts may be numerous, particularly when patients have nitrogen retention. The nonprotein nitrogen and the urea nitrogen of the blood are increased in about half the cases The rise begins in the 2nd week of illness and often follows a drop of blood pressure, although not invariably. Values between 100 and 200 mg. per 100 ml. for the blood nonprotein nitrogen have been observed with survival of the patient, but usually such levels presage fatal outcome A reduction in renal plasma flow may be responsible for the kidney damage The appearance of renal insufficiency as indicated by azotemia is one of the earliest laboratory findings of serious prognostic import; azotemia precedes death almost without exception. Changes in serum proteins are observed toward the end of the first week of illness; serum albumin is reduced, and serum globulin is increased, leading to a reversal of the albumin-globulin ratio Serum chlorides are usually reduced below 95 milliequivalents per liter, and values as low as 85 may be encountered; the chlorides in the urine are concomitantly reduced Carbon dioxide combining power of the blood is either normal or reduced, serum pH is normal in most instances. Likewise, values for plasma volume are within the accepted normal range The slight reduction in whole blood volume encountered toward the end of the disease in some patients is attributed to a reduction in red cell volume alone Roentgenograms of the chest frequently reveal a diffuse mottling of various areas in the lung field, often more extensive than the physical signs of pulmonary involvement would indicate. Transient abnormalities in the electrocardiogram have been recorded, these consist of low voltage of the QRS complexes, low or inverted T waves and, less often, depression of the S-T segment.

The clinical course of typhus is profoundly altered by treatment with the tetracyclines or chloramphenicol Within 12 to 24 hours

tion by developing a fever of several days' duration Infection is established in guinea pigs by the intra-abdominal inoculation of blood taken from a typhus patient during the febrile period. If the specimen is obtained in the first week of illness, whole blood may be used, after the 7th or 8th day of illness it is advisable to allow the specimen to clot, after centrifugation the serum is separated and stored for use in serologic tests, then the clot is ground with an equal volume of a sterile diluent, such as skimmed milk or the diluent referred to as "sucrose—PG," which is a solution containing sucrose, phosphate and glutamate (Bovarnick et al, 1950) After allowing gross particles to settle out, the suspension of ground clot is inoculated into 2 male guinea pigs, each weighing about 500 Gm.; each animal is given 4 to 5 ml Female pigs may be employed successfully, but, for reasons to be mentioned in the section on murine typhus, male guinea pigs are preferred Removal of the serum from the clot serves to increase the chance of successful detection of rickettsiae by eliminating antibodies which are present in the patient's blood serum after the 7th day of illness In some instances the pigs may be sick during the first 18 to 24 hours after the inoculation, probably as a consequence of the large volume of blood which is required for successful isolation of rickettsiae A small percentage of animals may succumb at this stage Usually, however, the animals remain entirely well after the inoculation, and the detection of the rickettsial infection depends solely on the temperature curve The normal morning temperature of a guinea pig varies between 38° and 39.5° C, values above 40.0° C are indicative of fever Ordinarily, guinea pigs which are inoculated with a patient's blood have a somewhat prolonged incubation period before their temperature exceeds 40.0° C, 12 to 24 days may elapse before the rise occurs When suspensions of brain or spleen of such animals are removed on the 3rd or 4th day of fever for subinoculation to fresh guinea pigs by the intra-abdominal route, the incubation period is shortened to 7 to 9 days and remains at this interval in successive transfers made in this manner

To accomplish a transfer, a febrile guinea pig is lightly anesthetized with ether and bled out from the heart, the brain is removed and ground to a 10 per cent suspension in a suitable diluent One or 2 ml. of the suspension is used for the intra-abdominal inoculation of each guinea pig in the next passage Spleen may be employed successfully instead of brain if taken on the 2nd or 3rd day of fever. The only evidence of infection with *R. prowazeki* to be observed grossly at the time of sacrifice of the guinea pig is a fibrinous exudate over the surface of the spleen; this is a constant finding on first passage as well as in subsequent transfers Direct smears made by scraping a few cells from the surface of the spleen just beneath this exudate, when stained appropriately, may contain a few large serosal cells in which rickettsiae are found It is extremely difficult to find cells containing rickettsiae in smears of spleen or tunica vaginalis in guinea pigs infected with epidemic strains unless the search is made on the 1st or 2nd day of the febrile reaction The fever may last for only 2 or 3 days, more commonly about a week, rarely longer than 10 days Guinea pigs survive typhus infection without sequelae unless the infecting dose is a massive one e g, large volume of infected yolk sac containing billions of rickettsiae per ml, in such circumstances the incubation period lasts only a few hours, and, in addition to fever, the animal may show enlargement of the scrotum and adhesions between the testes and the scrotal sac This "tunica reaction" or "scrotal swelling" was first observed by Neill in 1917 and further studied by Mooser in 1928, the phenomenon is sometimes called the Neill-Mooser reaction Although it may be observed in pigs infected with epidemic typhus, particularly if numerous rickettsiae are present in the inoculum, the reaction is more common in murine typhus

Guinea pigs do not develop a skin eruption as a consequence of typhus infection, but microscopic examination of the brain taken in the period from the 3rd or 4th day of fever up to a few days after the end of the fever shows the presence of many vascular lesions similar to those found in the brains of man and monkeys A serious disadvantage to the use of guinea pigs for the laboratory study of epidemic typhus is the fact that the only evidence of infection is obtained by taking the rectal temperatures daily for several

the central nervous system and the myocardium but are scattered widely throughout different organs of the body. Necrotic areas of the skin appear to be associated with thrombosis of capillaries, small arteries and veins, beginning in the corium Symmetrical gangrene of the extremities may be due to nerve lesions instead of thrombosis of large vessels. Lesions in the respiratory tract are similar to those in terminal bronchopneumonic processes in various diseases. Suggestive evidence of a rickettsial pneumonia has been reported (National Research Council, 1953).

Experimental Infection; Host Range

Epidemic typhus is a disease which occurs as a natural infection only of man, the human body louse, *Pediculus humanus corporis*, and the human head louse, *Pediculus humanus capitis*. The role of the human body louse in the transmission of typhus was first demonstrated experimentally by Nicolle, Comte and Conseil in 1909. The human body louse spends its entire existence in the clothes of man Eggs are laid in the seams of the undergarments After about 8 days, the eggs hatch, and the nymphs in the course of 2 weeks go through 3 moults to become adults The insects crawl about on the clothes, leaving the garments only to take a blood meal from their host. Lice cannot fly or jump but they have been observed to crawl for several yards. Each louse takes 4 to 6 blood meals a day from its host under natural conditions Human blood constitutes their only food Rickettsiae are present in the blood of patients suffering from typhus during the febrile period of the disease The body louse becomes infected by imbibing a blood meal containing rickettsiae, which then enter cells lining the intestinal tract of the louse. All stages of lice, whether newly hatched nymphs or fully developed adults, are susceptible to infection with *R. prowazeki*. After a few days the rickettsiae have multiplied so profusely that the cells containing them are swollen and may burst The organisms may then be passed in the feces of the louse or may enter uninvolved cells lining the intestinal tract. Ordinarily, rickettsiae appear in the feces of a typhus-infected louse about 3 to 5 days after the first infective meal. The louse usually succumbs to the infection after 7 to 10 days, but it is important to note that 24 days may elapse before all cells of the mid-intestine become full of rickettsiae.

Lice have been used extensively in typhus research. For this purpose a colony of normal stock lice is maintained by feeding twice daily on healthy human subjects The lice are confined in a small capsule covered with bolting silk which is strapped to the leg or the arm. Sometimes it is more convenient to store the capsule in an incubator between feedings. If the temperature of the incubator is lower than 30° C or higher than 37° C, rickettsiae may fail to develop; at temperatures above 37° C. the louse colony itself fares poorly. An ingenious technic was developed by Weigl in 1920 for the experimental infection of lice by means of a glass capillary inserted into the insect's rectum. Lice thus infected develop typhus which is similar in every respect to the infection acquired by feeding Although lice ordinarily do not thrive if they feed on other species than man, it has been possible to nourish them indefinitely on rabbits or to infect them by giving the rabbits a large inoculum of rickettsiae intravenously. More recently an artificial membrane has been developed for the experimental infection of lice (Haddon, 1956a, b), thereby permitting a wider range of experiments with these insects

Rickettsiae prowazeki are present only in the intestinal lining cells and the feces of infected lice; they have not been demonstrated in other tissues, such as the salivary glands They are not passed from generation to generation of lice in the egg. The course of typhus infection in the human head louse is identical with that in the body louse, but the latter is far more important in transmission of epidemic typhus

Monkeys, guinea pigs, rats and other rodents, developing chick embryos and certain arthropods are susceptible to experimental infection with epidemic typhus. Monkeys inoculated with *R. prowazeki* undergo a febrile illness of a few days' duration from which they survive. A skin eruption has been described in typhus-infected monkeys, but usually this is absent. The animals suffer loss of appetite and become apathetic, but otherwise exhibit no evidence of illness

Typhus was transmitted to guinea pigs by Nicolle, Conseil and Conor in 1911, who observed that the animals responded to inocula-

tion by developing a fever of several days' duration. Infection is established in guinea pigs by the intra-abdominal inoculation of blood taken from a typhus patient during the febrile period. If the specimen is obtained in the first week of illness, whole blood may be used; after the 7th or 8th day of illness it is advisable to allow the specimen to clot; after centrifugation the serum is separated and stored for use in serologic tests, then the clot is ground with an equal volume of a sterile diluent, such as skimmed milk or the diluent referred to as "sucrose—PG," which is a solution containing sucrose, phosphate and glutamate (Bovarnick et al, 1950). After allowing gross particles to settle out, the suspension of ground clot is inoculated into 2 male guinea pigs, each weighing about 500 Gm, each animal is given 4 to 5 ml. Female pigs may be employed successfully, but, for reasons to be mentioned in the section on murine typhus, male guinea pigs are preferred. Removal of the serum from the clot serves to increase the chance of successful detection of rickettsiae by eliminating antibodies which are present in the patient's blood serum after the 7th day of illness. In some instances the pigs may be sick during the first 18 to 24 hours after the inoculation, probably as a consequence of the large volume of blood which is required for successful isolation of rickettsiae. A small percentage of animals may succumb at this stage. Usually, however, the animals remain entirely well after the inoculation, and the detection of the rickettsial infection depends solely on the temperature curve. The normal morning temperature of a guinea pig varies between 38° and 39.5° C, values above 40.0° C are indicative of fever. Ordinarily, guinea pigs which are inoculated with a patient's blood have a somewhat prolonged incubation period before their temperature exceeds 40.0° C, 12 to 24 days may elapse before the rise occurs. When suspensions of brain or spleen of such animals are removed on the 3rd or 4th day of fever for subinoculation to fresh guinea pigs by the intra-abdominal route, the incubation period is shortened to 7 to 9 days and remains at this interval in successive transfers made in this manner.

To accomplish a transfer, a febrile guinea pig is lightly anesthetized with ether and bled out from the heart; the brain is removed and ground to a 10 per cent suspension in a suitable diluent. One or 2 ml. of the suspension is used for the intra-abdominal inoculation of each guinea pig in the next passage. Spleen may be employed successfully instead of brain if taken on the 2nd or 3rd day of fever. The only evidence of infection with *R. prowazeki* to be observed grossly at the time of sacrifice of the guinea pig is a fibrinous exudate over the surface of the spleen; this is a constant finding on first passage as well as in subsequent transfers. Direct smears made by scraping a few cells from the surface of the spleen just beneath this exudate, when stained appropriately, may contain a few large serosal cells in which rickettsiae are found. It is extremely difficult to find cells containing rickettsiae in smears of spleen or tunica vaginalis in guinea pigs infected with epidemic strains unless the search is made on the 1st or 2nd day of the febrile reaction. The fever may last for only 2 or 3 days, more commonly about a week, rarely longer than 10 days. Guinea pigs survive typhus infection without sequelae unless the infecting dose is a massive one, e.g., large volume of infected yolk sac containing billions of rickettsiae per ml., in such circumstances the incubation period lasts only a few hours, and, in addition to fever, the animal may show enlargement of the scrotum and adhesions between the testes and the scrotal sac. This "tunica reaction" or "scrotal swelling" was first observed by Neill in 1917 and further studied by Mooser in 1928, the phenomenon is sometimes called the Neill-Mooser reaction. Although it may be observed in pigs infected with epidemic typhus, particularly if numerous rickettsiae are present in the inoculum, the reaction is more common in murine typhus.

Guinea pigs do not develop a skin eruption as a consequence of typhus infection, but microscopic examination of the brain taken in the period from the 3rd or 4th day of fever up to a few days after the end of the fever shows the presence of many vascular lesions similar to those found in the brains of man and monkeys. A serious disadvantage to the use of guinea pigs for the laboratory study of epidemic typhus is the fact that the only evidence of infection is obtained by taking the rectal temperatures daily for several

weeks. Approximately 5 per cent of guinea pigs inoculated with fully virulent material fail to exhibit a febrile response.

The cotton rat (*Sigmodon hispidus*) has been very useful in quantitative studies with typhus rickettsiae. This species succumbs to infection following intracardial inoculation of 10^6 to 10^7 living typhus rickettsiae It develops a definite immunity by 21 days after intra-abdominal inoculation of very small numbers of rickettsiae; complement-fixation tests become strongly positive, and the animals then resist several fatal challenge doses The minimal number of typhus rickettsiae detectable in cotton rats is approximately the same as that required for detection in human body lice (Fuller, 1953, 1954). By contrast, several times as many are usually required for detection in guinea pigs

The white rat is not susceptible to infection with epidemic typhus in the usual sense, it undergoes only an inapparent infection An attempt to maintain a strain by serial passage in white rats usually is unsuccessful, a phenomenon of value in differentiating murine from epidemic typhus

The white mouse undergoes only an inapparent infection when inoculated by the intra-abdominal route with most strains of epidemic typhus if the inoculum contains relatively few *R prowazeki* However, it is possible to maintain a strain for several passages in mice by intra-abdominal inoculation of brain suspensions. Intranasal inoculation of rich suspensions of *R prowazeki* is followed by pulmonary consolidation and death; strains have been maintained in mice indefinitely by passage in this manner. Exposure of white mice to large doses of x-ray increases their susceptibility, and small numbers of rickettsiae given by the intra-abdominal route then produce a fatal infection within several days. Intravenous or intra-abdominal inoculation of concentrated suspensions of living, fully virulent rickettsiae into normal white mice is followed in a few hours by death of the animals as a consequence of a toxic reaction. The white rat also succumbs to the toxic property of epidemic typhus rickettsiae a few hours following intravenous inoculation of concentrated suspensions of the micro-organisms This phenomenon is discussed in the section on etiology.

Various other species have been employed in laboratory experiments with typhus, including the South African gerbil, *Tatera* [illegible] r- [illegible] s-pects of typhus studies. Under certain conditions a rich suspension of rickettsiae has been obtained from rabbit lungs following intratracheal inoculation. Giroud in 1938 showed that lesions in the skin of rabbits could be produced by intracutaneous inoculation of rickettsiae and that the technic provided possibilities for quantitative studies.

It should be emphasized that the attempt to recover typhus rickettsiae from a patient is a research problem not to be undertaken for ordinary diagnostic purposes because of the potential hazard to laboratory personnel

Etiology

The initial publications of Ricketts and Wilder (1910a, b) and von Prowazek (1914) were followed, after a period of some uncertainty as to the specific etiologic agent, by da Rocha Lima's studies (1916) which clearly implicated the micro-organisms which he named. The carefully controlled experiments of Wolbach et al. (1922) eliminated all doubts as to the causative relationship of *Rickettsia prowazeki* to epidemic typhus

There is remarkable variation in the size and the shape of typhus rickettsiae (Fig. 124) In smear preparations, they appear as minute coccoid or rod-shaped organisms, frequently occurring in pairs, sometimes in long chains, having a diameter of approximately 0 3 μ The organisms often have a bipolar appearance in stained preparations and when visualized by phase contrast microscopy (Ris and Fox, 1949). It is difficult to stain *R. prowazeki* by Gram's method. The method described by Macchiavello (1937) is the most satisfactory stain for rickettsiae.

Directions for Macchiavello's stain: Solutions· (A) 0.25 per cent basic fuchsin in distilled water; (B) *freshly prepared 0 25 to* 0.5 per cent citric acid; (C) 1 per cent methylene blue in distilled water. The slide is fixed lightly in heat, stained for 3 to 5 minutes with freshly filtered fuchsin; the fuchsin is poured off the slide which is then quickly dipped in the freshly prepared citric acid so-

lution, it is removed immediately and placed in a dish containing running tap water The final step is the flooding of the slide with methylene blue which is poured off after a few seconds The slide is then washed briefly in running tap water and dried with a piece of filter paper. Rickettsiae are stained a bright pink or red against a bluish background

R. prowazeki is relatively labile and easily killed by the common antiseptics such as formalin, phenol, merthiolate, etc Temperatures above 56° C. for 30 minutes result in its death. Viability may be retained in blood specimens at icebox temperature (+2° to +4° C.) for one or more days, but the organisms die in a few hours at room temperature or at 37° C. *R. prowazeki* in louse feces remains viable for several months if the temperature and the humidity are low Tap water, distilled water and ordinary physiologic saline have a deleterious effect on its viability, sterile skimmed milk or "sucrose PG" (Bovarnick, Miller and Snyder, 1950) is the most satisfactory medium for preserving viability of rickettsiae in suspensions The most satisfactory method of preserving rickettsiae is quick freezing in an alcohol-dry-ice mixture in a sealed glass ampule with subsequent storage in a dry-ice cabinet (−76° C.); in this state rickettsiae retain their viability for at least 16 years Rapid thawing is important, however, since slow return from the temperature of −76° C to room temperature results in great loss of viability Furthermore, even brief periods of storage at temperatures between −5° and −20° C may result in loss of viability Desiccation from the frozen state is satisfactory for storage of strains under appropriate circumstances By various technics evidence has been obtained which indi-

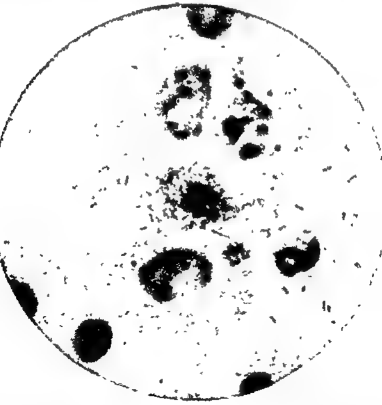

Fig 124 Microphotograph showing typhus rickettsiae inside and outside of cells Macchiavello's stain (×2000) (Photograph by Dr R M Allen)

cates that typhus rickettsiae contain carbohydrate-protein complexes, nucleic acids and lipids (Castaneda, 1934; Cohen and Chargaff, 1944; Cohen, 1950, Ris and Fox, 1949; Schaechter et al, 1957).

When care is taken to preserve the viability of typhus rickettsiae during purification procedures, it is possible to demonstrate that these micro-organisms have independent respiratory activity (Bovarnick and Snyder, 1949; Wisseman et al, 1951); the presence of a transaminase in rickettsiae has also been demonstrated (Bovarnick and Miller, 1950; Hopps et al, 1956)

Many attempts have been made, without success, to cultivate *R prowazeki* in cell-free media Cultivation in various types of tissue culture has been accomplished. Castaneda in 1939 showed that an abundance of rickettsiae could be obtained by the intranasal inoculation of rodents with murine typhus, his observations were extended to the epidemic strains by French workers (Durand and Giroud, 1940) The yolk-sac membrane of developing chick embryos was shown by Cox (1938, 1941, 1948) to be an excellent medium for the cultivation of *R. prowazeki* and several other species of rickettsiae In general, this technic is the most widely used at the present time Material containing rickettsiae is inoculated directly into the yolk sac of a 6- or 7-day-old embryonated hen's egg After several days' incubation at 34° to 36° C, the yolk-sac membrane is removed for examination or for subsequent inoculation into other chick embryos Such infected yolk-sac membranes may contain more than 10^9 viable rickettsiae per ml Successful isolation of *R. prowazeki* from the blood or the bone marrow of patients has been accomplished by direct inoculation of blood or ground clot into developing chick embryos Rickettsiae may be few or absent in stained smears of the yolk-sac preparation in the first few transfers but become very abundant in subsequent passages. An important characteristic of *R. prowazeki* is its location only in the cytoplasm of cells, never within nuclei This feature distinguishes the typhus group from the spotted fever group, members of which do invade nuclei

Infection with *R. prowazeki* evokes serologic responses in man and lower animals; specific antibodies can be demonstrated by fixation of complement, agglutination of rickettsiae, precipitin reactions, opsonic tests, and neutralization or protection tests. There is also a very important serologic test called the Weil-Felix reaction, the agglutination of Proteus OX 19 by sera of typhus patients Weil and Felix (1916) obtained from the urine of a typhus patient a proteus strain which was agglutinated not only by the serum of the original patient but also by the sera of other typhus patients Further study of various strains of proteus revealed that the one now called OX 19 is the most suitable for diagnosis of typhus. This phenomenon has been the subject of much experimentation, and numerous hypotheses have been advanced in its explanation Although no etiologic relationship has been detected between strains of this bacterium and typhus fever, Castaneda (1934) demonstrated a carbohydrate antigen common to Proteus OX 19 and to *R. prowazeki*. Although the Weil-Felix reaction occurs in more than 90 per cent of patients suffering from proved louse-borne typhus, the sera of typhus-infected guinea pigs and some other animals fail to develop agglutinins for Proteus OX 19.

Studies by Craigie and associates (1946), Fulton and Begg (1946), and Topping et al. (1945), demonstrated the existence of two components in *R. prowazeki*, a heat-labile component which is specific for *R. prowazeki* and a heat-stable component which is common to both *R prowazeki* and *R. mooseri* By repeated washing in a high-speed centrifuge (Plotz et al, 1948), the common antigen can be reduced to a low concentration, resulting in a considerable increase in specificity of some rickettsial suspensions

Living typhus rickettsiae, both *R. prowazeki*, and *R. mooseri*, are toxic for certain species if administered in highly concentrated suspensions (Gildemeister and Haagen, 1940, Neva and Snyder, 1952, 1955; Wattenburg et al, 1955). The toxicity is intimately related to living rickettsiae; the mode of action is believed to be a direct injury to the cells of the animal, usually the capillary endothelium with resultant leakage of plasma and death from progressive loss of circulating blood volume In rabbits, suspensions of *R. mooseri* cause lysis in vivo of red blood

cells and a rise in blood potassium which contributes to the manifestations of severe toxicity (Paterson et al, 1954)

The red blood cells of several species are lysed in vitro by typhus rickettsiae (Clarke and Fox, 1948, Snyder et al, 1954) It is probable that the phenomenon depends upon at least one and probably several enzymatic reactions, glutamate and magnesium are required for the reaction

Both the toxicity and the hemolysis can be neutralized by sera of man and lower animals convalescent from typhus Further studies by Topping and associates (1945), Hamilton (1945), and Craigie and associates (1946) indicate that the toxic factors of murine and epidemic rickettsiae are immunologically distinct

Diagnosis

Before the appearance of the characteristic rash, and on clinical grounds alone, it is impossible to assert with accuracy that a patient is suffering from typhus The clinical picture of the early stage of several acute infectious diseases closely resembles that of epidemic typhus Those which are likely to be confused with it are murine typhus, smallpox, relapsing fever, malaria, typhoid fever, meningococcic meningitis, measles and yellow fever The appearance and the evolution of the typhus rash serve to distinguish it from eruptions which are features of certain other acute infectious diseases In differentiating typhus from Rocky Mountain spotted fever it is helpful to recall that the rash in the latter disease ordinarily appears first on the exposed extremities and then extends to the trunk, frequently involving the face, the palms, and the soles as well The clinical diagnosis of epidemic typhus is particularly difficult in children or in persons who have previously received antityphus vaccine In such instances, the rash may be of very short duration or absent, the symptoms much less severe, and the duration of the fever as short as 3 to 5 days

Agglutinins for Proteus OX 19 appear in the sera of most typhus patients during the 2nd week of illness In a high proportion of cases, the titer rises to 1/160 or higher, often attaining values greater than 1/1,000 at the peak of the response which usually occurs in the 3rd week of illness or in the first 2 weeks of convalescence The Weil-Felix titer subsides to levels below 1/160 a few weeks after the end of the disease In exceptional cases, repeated examination of a patient's serum throughout the disease and early convalescence may reveal no rise in Weil-Felix titer, or the patient may succumb without a rise in titer being observed at any time An infection caused by *Proteus vulgaris* gives rise to agglutinins against Proteus OX 19 In rare instances, a person may be encountered whose serum agglutinates Proteus OX 19, although he is not currently suffering from typhus fever, if this is the case, the titer remains static, not exhibiting the rise and fall which is characteristic of the response to epidemic typhus A rise in titer from a low level (0 or 1/20) to more than double the original value may be of diagnostic significance, but it is more reliable to require values greater than 1/160 for diagnostic significance. The test can be performed with living or killed Proteus X 19 organisms, but care must be taken to use cultures which are in the "O" form Slide Weil-Felix tests have been developed which can be performed in 3 to 5 minutes at the bedside Different strains of proteus are used for diagnosis of other rickettsial diseases, principally OX 2 and OX K The sera of typhus patients may show a slight rise in agglutinins for OX 2 but very rarely any for OX K

Cox's development (1938) of the yolk-sac technic for the cultivation of rickettsiae made it possible to prepare large amounts of antigen for serologic tests Suspensions of rickettsiae derived from yolk sac after repeated washing yield specific antigens suitable for differentiation of antibodies of epidemic typhus from those of murine typhus in the sera of man and lower animals Complement-fixing antibodies may be detected in the sera of patients as early as the 7th or the 8th day of illness, they increase in titer, reaching a peak by the 12th to the 16th day after onset Subsequently, the titer usually falls slowly over a period of months to low values which may persist for years Occasionally, titers may fall to zero a few weeks after the end of the disease It may be difficult or impossible to differentiate epidemic typhus from murine typhus by complement-fixation tests

cates that typhus rickettsiae contain carbohydrate-protein complexes, nucleic acids and lipids (Castaneda, 1934; Cohen and Chargaff, 1944; Cohen, 1950; Ris and Fox, 1949; Schaechter et al., 1957).

When care is taken to preserve the viability of typhus rickettsiae during purification procedures, it is possible to demonstrate that these micro-organisms have independent respiratory activity (Bovarnick and Snyder, 1949, Wisseman et al., 1951); the presence of a transaminase in rickettsiae has also been demonstrated (Bovarnick and Miller, 1950; Hopps et al, 1956).

Many attempts have been made, without success, to cultivate *R. prowazeki* in cell-free media. Cultivation in various types of tissue culture has been accomplished Castaneda in 1939 showed that an abundance of rickettsiae could be obtained by the intranasal inoculation of rodents with murine typhus, his observations were extended to the epidemic strains by French workers (Durand and Giroud, 1940) The yolk-sac membrane of developing chick embryos was shown by Cox (1938; 1941, 1948) to be an excellent medium for the cultivation of *R. prowazeki* and several other species of rickettsiae In general, this technic is the most widely used at the present time. Material containing rickettsiae is inoculated directly into the yolk sac of a 6- or 7-day-old embryonated hen's egg After several days' incubation at 34° to 36° C, the yolk-sac membrane is removed for examination or for subsequent inoculation into other chick embryos Such infected yolk-sac membranes may contain more than 10^9 viable rickettsiae per ml. Successful isolation of *R. prowazeki* from the blood or the bone marrow of patients has been accomplished by direct inoculation of blood or ground clot into developing chick embryos Rickettsiae may be few or absent in stained smears of the yolk-sac preparation in the first few transfers but become very abundant in subsequent passages. An important characteristic of *R. prowazeki* is its location only in the cytoplasm of cells, never within nuclei. This feature distinguishes the typhus group from the spotted fever group, members of which do invade nuclei.

Infection with *R. prowazeki* evokes serologic responses in man and lower animals; specific antibodies can be demonstrated by fixation of complement, agglutination of rickettsiae, precipitin reactions, opsonic tests, and neutralization or protection tests. There is also a very important serologic test called the Weil-Felix reaction, the agglutination of Proteus OX 19 by sera of typhus patients Weil and Felix (1916) obtained from the urine of a typhus patient a proteus strain which was agglutinated not only by the serum of the original patient but also by the sera of other typhus patients. Further study of various strains of proteus revealed that the one now called OX 19 is the most suitable for diagnosis of typhus. This phenomenon has been the subject of much experimentation, and numerous hypotheses have been advanced in its explanation. Although no etiologic relationship has been detected between strains of this bacterium and typhus fever, Castaneda (1934) demonstrated a carbohydrate antigen common to Proteus OX 19 and to *R. prowazeki*. Although the Weil-Felix reaction occurs in more than 90 per cent of patients suffering from proved louse-borne typhus, the sera of typhus-infected guinea pigs and some other animals fail to develop agglutinins for Proteus OX 19.

Studies by Craigie and associates (1946), Fulton and Begg (1946), and Topping et al. (1945), demonstrated the existence of two components in *R. prowazeki*, a heat-labile component which is specific for *R prowazeki* and a heat-stable component which is common to both *R prowazeki* and *R mooseri* By repeated washing in a high-speed centrifuge (Plotz et al, 1948), the common antigen can be reduced to a low concentration, resulting in a considerable increase in specificity of some rickettsial suspensions

Living typhus rickettsiae, both *R. prowazeki*, and *R. mooseri*, are toxic for certain species if administered in highly concentrated suspensions (Gildemeister and Haagen, 1940; Neva and Snyder, 1952, 1955; Wattenburg et al, 1955). The toxicity is intimately related to living rickettsiae; the mode of action is believed to be a direct injury to the cells of the animal, usually the capillary endothelium with resultant leakage of plasma and death from progressive loss of circulating blood volume In rabbits, suspensions of *R. mooseri* cause lysis in vivo of red blood

trol of active delirium or restlessness and are preferable to morphine for this purpose Barbiturates should be avoided, since some typhus patients appear to react unfavorably to them. Codeine may be required for the relief of headache. Digitalis and other drugs which act principally on the heart are rarely indicated Oxygen by face mask or tent appears to make patients more comfortable when cyanosis is present, but it is doubtful whether oxygen administration has done more than prolong life for a few hours in cases with deep cyanosis The typhus-immune sera of man and several animal species have been administered to typhus patients (cf Snyder, 1948). A beneficial effect may be observed if potent immune serum is administered very early in the disease, but such sera are expensive and not generally available

The tetracyclines and chloramphenicol are highly effective in the treatment of experimental typhus infections (Ley and Smadel, 1954). Although relatively few patients with primary epidemic louse-borne typhus have been treated with these antibiotics, their efficacy in patients with scrub typhus and Rocky Mountain spotted fever gives assurance that they will be effective against epidemic typhus as well A clinician must choose the one that he prefers on the basis of his own experience These antibiotics are usually given by mouth, although preparations suitable for intravenous use are available The initial or loading dose is given in the course of 2 to 4 hours and depends on the body weight of the patient, from 2 to 3 Gm being used for a subject weighing 70 Kg The continuing dose thereafter is 1 to 2 Gm per 24-hour period, divided into 4 doses Response to the antibiotics is observed within 24 to 48 hours Progress of the clinical course is usually arrested at whatever stage the illness had attained when treatment was begun The temperature returns to normal, and concomitantly there is rapid subjective improvement in a patient's condition. Regardless of which antibiotic is used, it should be administered for 3 days after the temperature becomes normal, to reduce the incidence of recurrent bouts of fever which may occur if therapy is withdrawn prematurely.

Penicillin and streptomycin have a slight effect on experimental rickettsial infections, but their use in man is not indicated. Sulfonamides may have a deleterious effect on typhus and are contraindicated (Snyder, 1948) If the tetracyclines or chloramphenicol are not available, the use of para-aminobenzoic acid may have a beneficial influence if administered early in the disease in large doses (cf. Snyder et al, 1947)

Epidemiology

Epidemic typhus fever has occurred in cold climates over most of the world Epidemics ordinarily reach their peak in late winter and taper off in the spring Typhus thrives under conditions of human misery which predispose to an increase in louse infestation, such as crowding of people, lack of fuel, inadequate facilities for bathing, and weather so cold that the same garments are worn continuously day and night for months at a time Persons of all ages are susceptible to typhus In children under 15 years of age, the disease is mild, probably it occurs much more frequently in young children than has been reported As age increases, the case-fatality rate rises sharply, as shown in Tables 32 and 33 In certain epidemics the case-fatality rate has been greater in males than in females in the age groups from 20 to 50 (Ecke et al, 1945) There is considerable variation in the severity of typhus in different epidemics Over-all case-fatality rates for various epidemics range from less than 10 to more than 40 per cent Very little is known of the relative resistance of different races of people to the disease, and the effect of nutrition on resistance to the disease is not well understood An attack of epidemic typhus confers immunity which persists for many years Second attacks are discussed in the section on Brill-Zinsser disease A person who has recovered from epidemic typhus is immune to murine typhus, and vice versa

R prowazeki occurs in the blood of patients during the febrile period, the human body louse becomes infected by sucking blood from them Lice tend to leave a febrile patient in favor of persons with normal temperature They quickly abandon a corpse and seek a new host Whenever a louse bites, it makes a small puncture in the skin and defecates at the same time Since the louse bite is irritating, the bitten person usually scratches and may thus rub the feces of the louse into the injured skin Probably this is the usual way in which typhus infection is passed from man to man It is also possible

on the sera of persons who have previously been vaccinated with killed rickettsial vaccines (Plotz and Wertman, 1945; Zarafonetis et al., 1946, Smadel, 1948). In recent years it has become increasingly difficult to obtain highly specific washed rickettsial suspensions for use in the complement-fixation test, since the commercial sources have discontinued the manufacture of the antigen

Antibodies which agglutinate suspensions of rickettsiae can be demonstrated in the sera of man and certain animals following infection with typhus The test requires more skill for its performance and is considerably more expensive than the complement-fixation test (cf Smadel, 1948).

Tests for the presence of opsonins, precipitins and neutralizing antibodies are valuable in the study of typhus, but are practicable only for laboratories in which extensive work with rickettsial diseases is in progress (1) precipitins, Lim and Kurotchkin (1929), Topping et al. (1945), (2) opsonins, Epstein (1922); Castaneda (1936a), (3) neutralization and protection tests, Gildemeister and Haagen (1940); Giroud (1938), Clavero and Perez Gallardo (1943a), Topping et al (1945); van den Ende et al. (1946)

A serologic test was developed by Chang in 1953 which is based on the agglutination of sheep or human group O erythrocytes after sensitization with a serologically active fraction derived by treatment of rickettsiae with ether, heat and alkali (Chang, 1953, Chang et al, 1953, 1954). The active material was designated the "erythrocyte sensitizing substance," or ESS. Erythrocytes exposed to the typhus ESS are specifically agglutinated by sera of patients as early as the beginning of the 2nd week of the illness The anti-ESS antibodies persist in the patients' sera for long periods after recovery from the disease. The typhus ESS is common to both epidemic and murine species and is distinct from the antigens involved in complement-fixation, rickettsial agglutination, or the Weil-Felix reaction. The typhus ESS may have a slight antigenic overlap with the ESS derived from members of the Rocky Mountain spotted fever group. The ESS test is simpler to perform and less expensive than the complement-fixation test.

The fluorescent antibody technic as modified by Goldwasser and Shepard (1958) may provide a useful procedure for the laboratory diagnosis of typhus

Serologic technics are the methods of choice in the diagnosis of louse-borne typhus, since attempts to recover *R. prowazeki* by inoculation of animals, eggs or insects involve procedures which require special laboratory facilities as well as skill in interpretation of results. Thus, in order to establish definitely that *R prowazeki* has been isolated from a patient, it is necessary to demonstrate the development of specific antibodies, the absence of cultivable bacteria, the existence of reciprocal cross-immunity with known typhus strains, and the occurrence of specific pathologic lesions with typical intracellular rickettsiae

Treatment

All persons who handle typhus cases should be immunized To prevent lice from gaining access to their clothing, they should protect themselves carefully during the delousing of patients by the use of rubber gloves and surgical gowns. On admission to a hospital, a patient should be bathed with soap and water or 1 per cent solution of Lysol, and his clothes should be promptly disinfected, preferably by heat. A patient and his hospital garments should be carefully dusted with 10 per cent DDT delousing powder on admission to the wards and once a week thereafter until discharge. In order to disinfect and delouse a patient, formerly it was required that his head and axillary and pubic regions be shaved, this is no longer necessary. After the disinfestation procedures are completed, ordinary precautions are adequate.

Skillful and diligent nursing is of great importance. Constant supervision is necessary to prevent a delirious patient from doing himself bodily harm Stuporous patients or those in coma should be moved frequently from side to side to prevent bed sores. A rise of body temperature to 40 5° C or above should be treated promptly by cold sponges Oral hygiene is very important in the prevention of parotitis. Fluids should be administered at frequent intervals in adequate quantity to produce at least 1,500 ml. of urine daily A liquid or semisolid diet high in caloric content and in vitamins is desirable. Paraldehyde and chloral hydrate are valuable in the con-

tients and their clothes is described above under Treatment.

These recommendations may be amplified in regard to immunization and louse control. Both of these procedures are applicable to an individual as well as to a community. Vaccines for protection against epidemic typhus are of 3 general sorts.

1. The preferred type of antityphus vaccine contains killed *R. prowazeki* which cannot cause typhus. Adequate quantities of rickettsiae for such vaccines may be obtained from the intestines of human lice (da Rocha-Lima, 1918, Weigl, 1930), from rodent lungs (Castaneda, 1939, Durand and Giroud, 1940), from tissue cultures (Zinsser et al, 1938), and from the yolk-sac membrane of developing chick embryos (Cox, 1938, 1941, 1948; Craigie, 1945, Topping et al, 1945). The last, known as the Cox-type vaccine, was produced on a tremendous scale during World War II and was administered to several million troops who were sent to areas where they might be exposed to epidemic typhus. Civilian populations in certain of the danger zones were also given the vaccine (Table 34). Cox-type vaccine probably reduces the incidence of the disease in a group of exposed persons, but there are no data with satisfactory controls on this point. However, it has been definitely established that it reduces the mortality from typhus to practically zero. The course of the disease in persons immunized with this vaccine is milder and shorter than is that in unvaccinated persons, furthermore, the incidence of serious complications is sharply reduced (Ding, 1943, Ecke et al, 1945, Gilham, 1946).

In immunized American troops in World War II there were only 64 patients with mild epidemic typhus, all of whom recovered (Sadusk, 1947). The official recommendations for the Cox-type vaccine are 2 subcutaneous doses of 1 ml. each, separated by an interval of from 10 to 14 days, followed by a booster dose of 1 ml at the beginning and in the middle of the typhus season (Sadusk, 1947). Before receiving yolk-sac vaccine, persons should be asked if they are sensitive to egg proteins. If so, the use of the vaccine should be undertaken only with caution, since severe

reactions may occur. Complement-fixing antibodies may persist for several years after a course of Cox-type typhus vaccine, furthermore, a booster dose of 1 ml induces a rapid serologic response in persons immunized several years before, even though they may not have had demonstrable antibodies at the time the booster dose was given (Murray, Ofstrock and Snyder, 1952).

2. The second type is a vaccine prepared from "Strain E," a variant of epidemic typhus. This was discovered during World War II (Clavero and Gallardo, 1943b), and has been studied extensively in the past decade (Fox et al, 1957). Several thousand people have been inoculated with Strain E. Trials on small groups have shown that Strain E can induce immunity in man to direct challenge with a virulent epidemic strain. The rickettsiae in the vaccine are living, but they have lost the property of causing serious illness in man. Reactions have occurred after inoculation of the minimum immunizing dose of Strain E vaccine, but the long duration (at least 5 years) of the immunity from a single dose is a feature which may be of overriding importance under certain circumstances. Studies are in progress to determine the efficacy of Strain E vaccine in protection against naturally occurring epidemic typhus in Peru (Fox et al, 1955).

3. The third type of vaccine is composed of living murine rickettsiae treated with cer-

to become infected by crushing an infected louse on the skin, by rubbing infected louse feces into the eyes or by having dried infected louse feces gain access to the conjunctivae or to the mucous membranes of the respiratory tract. Once deloused and bathed, typhus patients are not capable of transmitting the infection to other persons by contact; *R prowazeki* does not occur in saliva, sputum, urine or feces of patients unless blood is also present With the exception of man, no other reservoirs of epidemic typhus are known

CONTROL MEASURES

The official recommendations of the American Public Health Association (1955, p. 205) should be followed by physicians who are faced with outbreaks of epidemic typhus "The most important measure for the rapid control of typhus, where the reporting has been good and the number of cases small, is the application of insecticides with residual effect to all contacts. Where the infection is known to be widespread, the systematic application of residual insecticide to all persons in the community is indicated." Immunization of persons in contact with cases is recommended; exposed susceptible persons, if louse infested, should be dusted with residual insecticide, quarantine is then unnecessary. The nearest World Health Organization Regional Epidemiological Information Station should be notified at once of the existence of a typhus epidemic. The disinfection of pa-

currence of wide swings, (3) the rash may be absent in many cases, (4) complications are much less frequent, except in persons of advanced age, and (5) the age-specific case-fatality rate is lower.

Pathologic Picture

Although the histopathology of Brill-Zinsser disease has not been studied extensively, the lesions which have been observed do not differ in any important respect from those found in the primary epidemic form of typhus fever

Experimental Infection, Host Range

The rickettsiae isolated from patients with Brill-Zinsser disease are indistinguishable from epidemic strains as regards experimental infection and host range (Murray and Snyder, 1951; Price et al, 1958)

Etiology

Extensive comparisons of 7 strains of Brill-Zinsser disease rickettsiae with standard epidemic and murine strains have established that this disease is caused by *R prowazeki*, not *R. mooseri* (cf Murray and Snyder, 1951, Price et al, 1958) It is erroneous to refer to "Brill's disease" as endemic or murine typhus, or to use the term "Brill's disease" to describe an illness transmitted to man by rat fleas (cf section on Murine Typhus)

Diagnosis

A diagnosis of Brill-Zinsser disease should be considered when a patient who has lived in a typhus zone develops a fever, a severe *intractable headache* and possibly a *macular* or maculopapular rash The diagnosis can be confirmed by the demonstration in serial serum specimens of a rising titer of antibodies which fix complement in the presence of epidemic typhus antigen or agglutinate suspensions of washed epidemic typhus rickettsiae There are two important differences between the serologic features of Brill-Zinsser disease and primary epidemic louse-borne typhus *The first difference is that in Brill-*Zinsser disease the rise in specific antibodies begins early, on the 4th to the 6th day after the onset of illness, the peak response is usually attained between the 8th and the 10th days (Murray et al, 1951) In the primary attack of epidemic typhus, on the other hand, the specific antibody rise begins later, about the 8th to the 12th day with maximum titers being reached from the 12th to the 16th day after onset (Plotz et al, 1948) *The second* important serologic difference is that the Weil-

Table 35 Differences Between Primary Attacks and Recrudescences of Epidemic Typhus

Primary Epidemic Louse-Borne Typhus		Brill-Zinsser Disease
No	History of Previous Attack of Typhus	Yes

Transmitted by human body lice	Relation to Lice	Can occur in absence of lice
12 to 18 days	Usual Duration of Fever	7 to 11 days
	Complement-Fixation Test	
Less than 1/100	(a) Titer on 8th day of illness	More than 1/1,000
Later than 12th day	(b) Maximum titer occurs	*Between 8th and 10th day*
	Weil-Felix Test	
Usually from 1/320 to 1/5,000	Maximum titers	Usually less than 1/160

tain agents in an effort to attenuate the organisms (Laigret and Durand, 1939; Blanc and Baltazard, 1941). These living vaccines have been used on a very large scale for immunization of natives in French North Africa (cf. Biraud, 1943), but their use is not without danger, since they cause attacks of murine typhus. deaths have been recorded (Palacios et al , 1935, Sadusk and Kuhlenbeck, 1946)

The efficacy of delousing in controlling epidemics was shown in North Africa in 1912 (Otto and Munter, 1930) and in Serbia in 1915 (Strong et al , 1920) At that time and until very recently, in order to be deloused it was necessary for infested persons to remove all clothes, which were then subjected to heat while they bathed When large groups were involved, this process was very cumbersome, expensive and time-consuming

The disadvantages of delousing by heat were eliminated in 1943 when various antilouse powders were developed and methods devised (Wheeler, 1943, Soper et al , 1945) whereby large numbers of people could be treated without removing their garments The powders were shown to be effective when blown into the hair, up the sleeves, down the neck and around the waist into trousers The now famous insecticide, DDT, dichloro-diphenyl-trichloro-ethane (Mooser, 1942; Bishopp, 1945, Knipling, 1948), proved to be nearly ideal

The most satisfactory property of DDT is the persistence of its lethal effect on lice for more than 2 weeks after being dusted into the garments, or for more than 4 weeks after impregnation from an emulsion Reinfestation of dusted persons was reduced to a negligible degree by this persisting effect of DDT. The final improvement in delousing technic was the development of a power duster, a device consisting of an air compressor which operates 10 dust guns simultaneously, the technic has been described by Greeley (1948)

Recent reports indicate that human body lice in several areas have become partially or highly resistant to DDT (Hurlbut et al., 1954, Eddy et al , 1955, and Wright and Brown, 1957). In such circumstances insecticides, preferably with residual effect, must be used for effective louse control (Cole and Burden, 1956).

BRILL-ZINSSER DISEASE (RECRUDESCENT TYPHUS)

(Synonym: Sporadic typhus)

Introduction

Brill-Zinsser disease is a recrudescence of epidemic louse-borne typhus fever in relatively mild form years after the primary attack

History

In 1898, Brill noted the occurrence in New York City of a disease resembling typhus fever Cases continued to appear sporadically in that city and elsewhere No association with human body lice could be established Anderson and Goldberger (1912) showed that the disease was a form of typhus by transmitting the infection to monkeys and by

parts of eastern Europe. However, in the period preceding the recognition of murine flea-borne typhus, all sporadic cases of typhus in the United States were customarily referred to as Brill's disease; this fact resulted in much confusion (cf section on Murine Flea-borne Typhus).

Zinsser (1934), after scrutinizing the records of 538 cases of "Brill's disease," advanced his hypothesis that the disease is a recrudescence of epidemic typhus in persons who suffered an attack of the classic disease many years previously while residing in areas where epidemics of typhus were occurring Zinsser postulated the persistence of the typhus rickettsiae during the latent interval somewhere in the tissues of the human subject Zinsser's hypothesis has been verified in large part by recent studies The term Brill-Zinsser disease was proposed by Loeffler and Mooser in 1952 in recognition of Zinsser's appreciation of the epidemiologic significance of the disease.

Clinical Picture

The factors which precipitate Brill-Zinsser disease are not known, consequently, there are no data on the incubation period. Clinical features are those of epidemic louse-borne typhus with the following exceptions: (1) Brill-Zinsser disease is shorter in duration (7 to 11 days); (2) the temperature curve is more irregular with a tendency for the oc-

currence of wide swings; (3) the rash may be absent in many cases; (4) complications are much less frequent, except in persons of advanced age; and (5) the age-specific case-fatality rate is lower

Pathologic Picture

Although the histopathology of Brill-Zinsser disease has not been studied extensively, the lesions which have been observed do not differ in any important respect from those found in the primary epidemic form of typhus fever

Experimental Infection, Host Range

The rickettsiae isolated from patients with Brill-Zinsser disease are indistinguishable from epidemic strains as regards experimental infection and host range (Murray and Snyder, 1951, Price et al, 1958)

Etiology

Extensive comparisons of 7 strains of Brill-Zinsser disease rickettsiae with standard epidemic and murine strains have established that this disease is caused by *R prowazeki*, not *R mooseri* (cf Murray and Snyder, 1951, Price et al, 1958) It is erroneous to refer to "Brill's disease" as endemic or murine typhus, or to use the term "Brill's disease" to describe an illness transmitted to man by rat fleas (cf section on Murine Typhus)

Diagnosis

A diagnosis of Brill-Zinsser disease should be considered when a patient who has lived in a typhus zone develops a fever, a severe intractable headache and possibly a macular or maculopapular rash The diagnosis can be confirmed by the demonstration in serial serum specimens of a rising titer of antibodies which fix complement in the presence of epidemic typhus antigen or agglutinate suspensions of washed epidemic typhus rickettsiae There are two important differences between the serologic features of Brill-Zinsser disease and primary epidemic louse-borne typhus The first difference is that in Brill-Zinsser disease the rise in specific antibodies begins early, on the 4th to the 6th day after the onset of illness, the peak response is usually attained between the 8th and the 10th days (Murray et al, 1951) In the primary attack of epidemic typhus, on the other hand, the specific antibody rise begins later, about the 8th to the 12th day with maximum titers being reached from the 12th to the 16th day after onset (Plotz et al, 1948) The second important serologic difference is that the Weil-

Felix reaction (agglutination of Proteus OX 9) usually is negative in Brill-Zinsser disease (Murray et al, 1951).

The differences between primary epidemic typhus and Brill-Zinsser disease are summarized in Table 35 (modified from Murray and Snyder, 1953).

At least 30 per cent of persons who formerly lived in an epidemic typhus area can be expected to have residual antityphus complement-fixing and neutralizing antibodies, even though 40 to 50 years may have elapsed since their last possible exposure to typhus (Murray et al, 1952; Price et al, 1958). Thus, a definite rise in titer of more than 4-fold in the complement-fixation test with epidemic typhus antigen must be demonstrated in association with a particular illness in such persons in order to establish a diagnosis of Brill-Zinsser disease by serologic procedures.

Antibodies which fix complement in the presence of murine typhus antigen may also develop during the disease However, the maximum titers are regularly lower than those with epidemic antigen when the highly specific washed rickettsial suspensions are used as test antigens (Murray et al, 1950).

Treatment

The tetracyclines or chloramphenicol can be expected to exert a beneficial effect on Brill-Zinsser disease, although the evaluation of such therapy is more difficult because of the relatively short and mild course of the untreated disease

Epidemiology

Brill-Zinsser disease has been recognized in persons who migrated to several countries in which epidemic louse-borne typhus is not present, namely, the United States (Brill, 1910; Zinsser, 1934; Morgan et al., 1948; and Murray et al., 1950), Switzerland (Mooser and Loeffler, 1946), England (Hawksley and Stokes, 1950), France (Giroud et al., 1950, Worms, 1950) Portugal (Soares, 1950), and Poland (Kostrzewski et al., 1957). The illness is by no means restricted to that portion of a population which has migrated away from a typhus zone In a very brief interval in the summer of 1950, Murray and his associates identified 26 cases in a relatively small part of Yugoslavia, an area which had been swept over by louse-borne typhus in 1944-45 (Murray et al, 1951). These cases were about equally distributed between males and females; the age range was 9 to 56 years; there were no secondary cases; there was no association with human body lice, nearly all of the patients gave a clear history of a previous attack of typhus which occurred during the louse-borne epidemics of 1944-45. Only one of the cases was sufficiently like epidemic typhus to appear in the official case reports These observations indicate several features of importance epidemiologically:

(1) Brill-Zinsser disease can be expected to occur in the native population of typhus zones as well as in persons who migrate to nontyphus zones; (2) the disease definitely is not restricted to any one race, sex or age group; (3) the incidence of Brill-Zinsser disease may be considerably greater than formerly suspected; (4) many of the hundreds of thousands of displaced persons who recently have settled in nontyphus zones are notorious concentration camps (Snyder, 1947); (5) Brill-Zinsser disease probably will not be recognized unless physicians are alert to the mild course, the frequent absence of a rash, and the negative Weil-Felix reaction

No clues have been obtained as to factors which precipitate the recrudescence of typhus It is believed that after a person recovers from primary louse-borne typhus the rickettsiae remain viable somewhere in his tissues. The balance between the immune mechanism and the parasite is disturbed somehow, and a recrudescence occurs The early serologic response in Brill-Zinsser disease and its milder course strongly suggest that partial immunity is still present. Price (1955) isolated virulent epidemic typhus rickettsiae from the lymph nodes of two "healthy" subjects who had resided in a typhus zone early in their lives but who had been continuously in an environment believed to be completely free of epidemic typhus for more than a decade prior to the recovery of the organisms from their lymph nodes Both of these subjects had low-titer antibodies in their sera, indicating previous typhus infection. Neither subject had clinical signs or symptoms suggestive of active infection

fered this suggestion, predicting that human body lice might become infected if they fed upon patients with Brill-Zinsser disease. This has now been conclusively demonstrated, 7 patients studied in the United States were infectious for lice which were allowed to feed on them at some time before the 8th day of the illness (Murray et al, 1950) The typhus rickettsiae in these lice were fully virulent, indistinguishable from the classic strains (Murray and Snyder, 1951) Thus, under disturbed conditions in a community which permit the development of louse infestation, patients with Brill-Zinsser disease may be the foci from which an epidemic of louse-borne typhus fever may spread to susceptible persons in the population Murray and his associates in Yugoslavia (1958) have identified several small outbreaks of louse-borne typhus which clearly originated in a case of Brill-Zinsser disease The differentiation was accomplished on the basis of the distinctive serologic patterns the very rapid rise in complement-fixing antibodies early in Brill-Zinsser disease permits identification of the recrudescent cases from the primary louse-borne cases The fact that the outbreaks noted by Murray remained small and sharply localized is compatible with absence of overcrowding and with relatively low rates of louse infestation in the areas at the time of the studies

Control Measures

There are no control measures which are known to be effective in reducing the incidence of Brill-Zinsser disease If such cases occur in the presence of louse infestation, the situation should be regarded potentially as the beginning of an epidemic, and those measures described for the control of epidemic louse-borne typhus should be applied

MURINE TYPHUS (FLEA-BORNE)

(Synonyms Endemic typhus, urban or shop typhus of Malaya, flea typhus, rat typhus)

Introduction

Murine typhus is a relatively mild, acute febrile illness of 9 to 15 days' duration, characterized by headache and macular rash It is a natural infection of rats and mice transmitted sporadically to man by the rat flea, *Xenopsylla cheopis* The etiologic agent is *Rickettsia mooseri* (Monteiro, 1931) The case-fatality rate for all ages is approximately 2 per cent.

History

Murine typhus probably has occurred since ancient times, but only in recent years has it been differentiated from epidemic louse-borne typhus Although sporadic cases of typhus in Europe had been referred to occasionally (McCrae, 1907), such reports received little notice In the United States, sporadic cases of typhus were noted by Brill (1910), Lee (1912) and Paullin (1913) Hone (1922) described several isolated cases in Australia, and Wheatland (1926) called attention to the occurrence of a noncontagious typhuslike fever among the farm population in Queensland, at a time when a plague of mice afflicted the region Sinclair and Maxcy (1925) and later Maxcy (1926, 1929) investigated cases of "endemic" typhus in southeastern United States On epidemiologic grounds, Maxcy (1929) postulated that a reservoir of the disease other than man exists and mentioned that rats and mice might serve as such a reservoir He also mentioned that fleas, mites or ticks might be the vectors The epidemiologic evidence for postulating a separate variety of typhus was strengthened by observations of differences in the pathologic features (Wolbach and Todd, 1920) and in the characteristics of strains isolated from the sporadic cases of typhus in Mexico Neill (1917) observed that male guinea pigs inoculated with typhus strains obtained from Mexico exhibited enlargement of the scrotal sac and adhesions of the testes Mooser (1928) reported that certain strains of typhus rickettsiae isolated from patients in Mexico not only caused the tunica reaction in male guinea pigs but also multiplied profusely in the serosal cells over the testes The tunica reaction of guinea pigs has been referred to as the "Neill-Mooser reaction" and the cells packed with rickettsiae as "Mooser cells" The final steps proving the existence of a second variety of typhus were made by Dyer, Rumreich and Badger (1931) who isolated rickettsiae from rat fleas in Baltimore, and by Mooser, Castaneda and Zinsser (1931a) who found the typhus agent in brains of rats trapped in Mexico City. The disease was then named murine typhus to indicate its presence as a natural infection of rats (Mooser, 1932) It was promptly sought for and found in most parts of the world (Biraud and Deutschman, 1936) Biologic differences between typhus strains isolated from rats or

fleas and those isolated from patients suffering from classic louse-borne epidemic typhus were demonstrated by Zinsser and his colleagues (Zinsser, 1940, Mooser, 1945). The two varieties of typhus were further characterized by application of serologic technics (Smadel, 1948) and by cross-vaccination experiments (Topping et al, 1945; Craigie et al, 1946, Murray and Snyder, 1951).

Clinical Picture

Murine typhus in man is similar to epidemic louse-borne typhus In the absence of epidemiologic and laboratory data, it is impossible on the basis of clinical findings alone to determine whether a patient is suffering from murine typhus instead of epidemic typhus However, murine typhus is relatively mild with a negligible mortality except in persons more than 50 years old The onset is likely to be more gradual than that of epidemic typhus, the symptoms less severe, the rash shorter in duration, and the skin lesions less numerous The central nervous system, the myocardium and the kidneys are involved less severely. Complications, e g, parotitis, necrosis of the skin, gangrene of the extremities, otitis media, furunculosis, azotemia and bronchopneumonia, occur infrequently The temperature curve usually shows wider fluctuations than that of epidemic typhus The febrile period is terminated by rapid lysis after 9 to 14 days Recovery is prompt without sequelae Laboratory data are similar to those described for epidemic typhus, except that abnormal findings tend to be slight or absent in murine typhus Clinical features are described in detail by Maxcy (1926), Miller and Beeson (1946), and Woodward (1948)

Pathologic Picture

The pathology of murine typhus in man probably is similar to that of epidemic typhus However, there is a paucity of data on this point, since very few postmortems have been reported in cases of proved murine typhus.

Experimental Infection; Host Range

Murine typhus occurs as a natural infection of rats and mice. It is transmitted from rat to rat either by the rat louse, ***Polyplax spinulosus*** (Mooser, Castaneda and Zinsser, 1931b), or by the rat flea, ***Xenopsylla cheopis*** (Dyer, Rumreich and Badger, 1931). Transmission from rat to man is attributed to *X* ***cheopis*** The infection in man is an accidental occurrence, unconcerned in the maintenance of the infection in nature Some observers (Zinsser, 1937) regard the present evidence sufficient to establish the fact that murine typhus may be spread from man to man in epidemic form by the human body louse (Mooser, 1945). Many species in addition to those mentioned are susceptible to murine typhus: monkeys, donkeys, cats, squirrels, deer mice, voles, gerbilles, cotton rats, guinea pigs, developing chick embryos, cat fleas, tropical rat mites, etc ; see articles by Wolbach (1940) and Philip (1948)

The rat flea, *X.* ***cheopis,*** becomes infected by feeding on a rat which is in the acute phase of an infection The rickettsiae multiply in the cells of the flea without causing damage to the host. Once infected, the flea continues to discharge rickettsiae in its feces for the duration of its life. Other species of fleas, notably ***Pulex irritans,*** are susceptible, but their reaction to typhus infection has not been thoroughly studied When human body lice are experimentally infected with murine typhus, the resulting disease is similar in all respects to the infections caused by epidemic strains (Mooser, 1945) Whether or not lice acquire murine typhus under natural conditions is open to question, experimental passage of 2 strains of murine typhus serially in human body lice for several transfers was not accompanied by any change in characteristics toward epidemic strains (Murray and Snyder, 1951)

Murine typhus can be established in guinea pigs by intra-abdominal inoculation of the blood of a patient by the method described for epidemic typhus The infection, once established in serial passage in these animals, has an incubation period of from 3 to 7 days The temperature curve often exhibits fluctuations but tends to stay at or above 40° C. for several days. The fever is usually accompanied by enlargement of the scrotal sac of male guinea pigs, reddening of the skin of the scrotum, and adhesions between testes and tunica vaginalis This "tunica reaction" is quite distinct from the more severe "scrotal reaction" caused by spotted fever. In the latter, necrosis of the scrotal skin often occurs. When an animal is sacrificed on the 1st or

2nd day of the tunica reaction, two phenomena are observed at necropsy the spleen is covered by a thin coat of fibrin which may cause the spleen to adhere to the abdominal wall, and the testes may show adhesions and a few small subserosal hemorrhages Smear preparations from the surface of the testes, the peritoneum, or the spleen contain numerous rickettsiae, intracellular and extracellular in location Transfer to other guinea pigs is accomplished by removing the spleen, grinding it in a mortar with sterile sand or alundum to a 10 per cent suspension in a suitable diluent, after gross particles are removed by light centrifugation, the supernatant suspension in 1 or 2 ml. amounts is inoculated intra-abdominally into fresh normal male guinea pigs An alternate method of transfer is the use of a suspension obtained by shaking the testes in a flask with glass beads and 20 to 30 ml of a suitable diluent The materials prepared in this manner on the 1st or 2nd day of the tunica reaction contain at least 10^6 viable rickettsiae per ml It is a common observation that during the hot summer months, murine typhus tends to lose its distinguishing features in guinea pigs, but in the cold months the fever and tunica reaction reappear Great reliance was formerly placed on the tunica reaction of guinea pigs as a means of differentiating between the epidemic and the murine varieties More extensive experience has shown that occasionally epidemic strains may produce the tunica reaction, and conversely, that a murine strain may fail to cause it Specific serologic tests and cross-vaccination experiments now provide such reliable and rapid differentiation between epidemic and murine strains that the tunica reaction of guinea pigs is no longer relied upon to distinguish one variety from the other

Murine typhus may be maintained indefinitely by passage in white rats, whereas epidemic strains die out after a few passages Murine rickettsiae usually multiply profusely in the cells of the peritoneum and may cause fever and scrotal swelling, but the animals recover as a rule An important feature of the murine infection in rats is the persistence of viable rickettsiae in the brain for several months (Philip, 1948) Large doses of *R mooseri* may produce death of white mice within a few hours as a consequence of their toxic properties (Gildemeister and Haagen, 1940) Slightly smaller doses cause extensive peritonitis with death of the animals in 3 to 8 days Enormous numbers of rickettsiae are found in the peritoneal exudate of moribund mice. Inocula containing relatively few *R mooseri* render mice immune with 3 weeks to toxic and infective doses of the organism Rats and mice, as well as sheep, dogs and rabbits, may be infected by the intranasal route and succumb in a few days with extensive pneumonitis This procedure has been utilized for vaccine production Irradiation of white rats and cotton rats with deep x-rays greatly increases the yield of murine typhus rickettsiae in these animals

Etiology

The causative agent of murine typhus has been named *Rickettsia mooseri* (Monteiro 1931) in honor of Mooser and is similar to *R prowazeki* as regards size shape, staining properties, and resistance to chemical and physical agents but exhibits less pleomorphism Antigenic composition has been described in the section on etiology under epidemic typhus *R. mooseri* has been cultivated in the yolk-sac membrane of developing chick embryos with considerable success (Cox, 1938)

Diagnosis

Epidemic typhus and murine typhus cannot be distinguished solely on clinical grounds in individual cases Since murine typhus may exist in the same regions with Rocky Mountain spotted fever (United States, Mexico, South America, probably India), it may be emphasized that the rash of typhus appears on the body first, then spreads to the extremities, whereas in spotted fever the reverse is true The rash of the latter disease has a greater tendency to be papular and to become petechial or hemorrhagic Isolation of *R mooseri* can be accomplished by inoculation of white rats or guinea pigs with the blood of a patient Comments in the section on epidemic typhus in regard to use of ground clot apply equally well to murine typhus Direct isolation of murine typhus strains by inoculation of human blood into developing chick embryos, although entirely feasible, has not been reported The Weil-Felix reaction occurs in murine as well as in epidemic typhus.

TABLE 36 MURINE TYPHUS IN THE UNITED STATES

YEAR	CASES *	DEATHS †
1931	332	22
1936	1,732	112
1941	2,780	135
1946	3,365	128
1951	378	16
1956	98	Not Available

* Cases have been reported from more than three fourths of the states In the entire United States, from 1931 through 1946, approximately 42,000 cases were reported

† Figures taken from Supplements to Public Health Reports, U S Pub Health Service

The complement-fixation test, the agglutination of rickettsiae, and the neutralization of toxic properties have been discussed in the section on epidemic typhus. There are no important differences between the 2 types of typhus in regard to the time of appearance, peak of occurrence, or persistence of the various antibodies Sera of animals and man in convalescence from attacks caused by proved murine typhus strains usually have higher titers against homologous than against heterologous antigens Sera of patients who contract murine typhus after having received killed vaccine of the epidemic type may show no difference in titer when tested against the 2 antigens (Plotz and Wertman, 1945; Zarafonetis et al, 1946)

TREATMENT

Treatment of murine typhus differs in no important respect from that described for epidemic typhus The mildness of the disease and its slower onset tend to delay its clinical recognition until the optimum period for administration of antibiotics has passed

EPIDEMIOLOGY

Murine typhus is world-wide in distribution. In the United States, the reported cases from 1931 to 1956 (Table 36) indicate an increase in prevalence which seems to be of greater magnitude than can be accounted for on the basis of improved diagnosis In the years 1948 to 56, however, a sharp decline occurred in the reported cases of murine typhus in the United States Maximum incidence occurs in the summer and fall months

in part to difficulty in recognizing the rash in dark-skinned individuals Persons of both sexes are equally susceptible to the illness. The most important factor influencing the occurrence of murine typhus in human beings is residence or occupation in areas where rats abound. Although the disease often involves only one member of a household, it may appear in several occupants of a dwelling The usual manner in which the infection is transmitted to man is as follows: at the time an infected flea sucks blood, it deposits feces which may be scratched into the wound made by the bite. There are other possible modes of infection, for example, infected flea feces may gain access to the conjunctivae or mucous membranes of the respiratory tract, experiments with volunteers have shown that murine typhus can be contracted by the ingestion of viable *R. mooseri* (Pollard et al, 1946); it is possible that cases may be caused by eating food recently contaminated by the urine of infected rats. A patient suffering from murine typhus cannot transmit the infection to other persons by contact; *R. mooseri* does not occur in the sputum, the feces or the urine unless gross blood is also present. An attack of the disease results in immunity which persists for many years.

As knowledge of the differences between epidemic typhus and murine typhus has accumulated, it has become evident that both types are present in Mexico, and that epidemic strains are frequently isolated in that country from patients (Varela and Zozaya, 1945) Moreover, complement-fixation tests on sera of residents of Mexico indicate the preponderance of the classic infection in that region (Silva-Goytia, 1944) Therefore, the term "Mexican typhus" is ambiguous and should be avoided.

The relationship of murine to epidemic typhus has been the subject of much speculation One theory postulates that murine typhus is the more ancient disease as shown by the fact that the two principal hosts of *R. mooseri*, the rat and the rat flea, undergo no harmful effects from their intimate association with it. By contrast, *R. prowazeki* causes a serious illness in man and a fatal infection in the louse. These facts have been taken as evidence that, from the evolutionary viewpoint, the association of man and human lice with typhus rickettsiae is relatively recent.

Control Measures

The official recommendations of the American Public Health Association (1955, pp 206-7) are as follows:

A. Preventive measures

1. Application of insecticide powders with residual activity (10% DDT or other compounds) to rat runs, burrows, and harborages

2. Rodent control measures should be delayed until flea populations have been reduced by insecticides, to avoid temporary increase in cases

B Control of the infected individual, contacts and environment

1. Report to local health authority. Case report obligatory in most states and countries
2. Isolation. None
3 Concurrent disinfection None
4. Terminal disinfection None
5 Quarantine None

[illegible]

6 Specific treatment As for epidemic typhus

C Epidemic measures In endemic areas with numerous cases, widespread use of DDT has markedly reduced the flea index of rats, and incidence of infection in rats and man Inoculation with an inactivated *R mooseri* vaccine may be useful for limited groups in hazardous occupations but the efficiency of specific therapy eliminates the need for general protection of populations

D. International measures None

Measures for protection of individuals against murine typhus, such as the wearing of flea-proof garments, are impracticable Vaccines containing killed *R mooseri* afford protection in laboratory tests, but it is debatable whether vaccination of man is advisable *as a control measure, except for persons* who are frequently exposed to the infection More data are needed in regard to the efficacy of murine vaccine for human use It should be emphasized that, although an attack of epidemic typhus protects against murine typhus and vice versa, vaccines made from dead rickettsiae satisfactorily protect only against homologous strains To achieve protection against murine typhus, vaccines should be made with *R mooseri*, not *R prowazeki*. Considerable progress in the control of murine typhus on a community-wide basis has been made in three directions (1) ratproofing of buildings; (2) reducing flea populations through the use of DDT on rat runs; and (3) poisoning of rats with alpha naphthyl thiourea, warfarin (Hayes and Gaines, 1950) and other rodenticides The use of DDT should precede rat-poisoning campaign in order to kill potentially infected fleas before their hosts are poisoned Otherwise there may be a temporary increase in cases of murine typhus (Davis, 1947, Bradley and Wiley, 1948)

TABLE 36 MURINE TYPHUS IN THE UNITED STATES

YEAR	CASES *	DEATHS †
1931	332	22
1936	1,732	112
1941	2,780	135
1946	3,365	128
1951	378	16
1956	98	Not Available

* Cases have been reported from more than three fourths of the states In the entire United States, from 1931 through 1946, approximately 42,000 cases were reported

† Figures taken from Supplements to Public Health Reports, U S Pub Health Service

The complement-fixation test, the agglutination of rickettsiae, and the neutralization of toxic properties have been discussed in the section on epidemic typhus. There are no important differences between the 2 types of typhus in regard to the time of appearance, peak of occurrence, or persistence of the various antibodies. Sera of animals and man in convalescence from attacks caused by proved murine typhus strains usually have higher titers against homologous than against heterologous antigens Sera of patients who contract murine typhus after having received killed vaccine of the epidemic type may show no difference in titer when tested against the 2 antigens (Plotz and Wertman, 1945; Zarafonetis et al., 1946).

TREATMENT

Treatment of murine typhus differs in no important respect from that described for epidemic typhus The mildness of the disease and its slower onset tend to delay its clinical recognition until the optimum period for administration of antibiotics has passed

EPIDEMIOLOGY

Murine typhus is world-wide in distribution In the United States, the reported cases from 1931 to 1956 (Table 36) indicate an increase in prevalence which seems to be of greater magnitude than can be accounted for on the basis of improved diagnosis In the years 1948 to 56, however, a sharp decline occurred in the reported cases of murine typhus in the United States. Maximum incidence occurs in the summer and fall months [illegible]

in part to difficulty in recognizing the rash in dark-skinned individuals. Persons of both sexes are equally susceptible to the illness The most important factor influencing the occurrence of murine typhus in human beings is residence or occupation in areas where rats abound. Although the disease often involves only one member of a household, it may appear in several occupants of a dwelling. The usual manner in which the infection is transmitted to man is as follows, at the time an infected flea sucks blood, it deposits feces which may be scratched into the wound made by the bite. There are other possible modes of infection, for example, infected flea feces may gain access to the conjunctivae or mucous membranes of the respiratory tract; experiments with volunteers have shown that murine typhus can be contracted by the ingestion of viable *R. mooseri* (Pollard et al., 1946); it is possible that cases may be caused by eating food recently contaminated by the urine of infected rats. A patient suffering from murine typhus cannot transmit the infection to other persons by contact; *R mooseri* does not occur in the sputum, the feces or the urine unless gross blood is also present. An attack of the disease results in immunity which persists for many years.

As knowledge of the differences between epidemic typhus and murine typhus has accumulated, it has become evident that both types are present in Mexico, and that epidemic strains are frequently isolated in that country from patients (Varela and Zozaya, 1945) Moreover, complement-fixation tests on sera of residents of Mexico indicate the preponderance of the classic infection in that region (Silva-Goytia, 1944) Therefore, the term "Mexican typhus" is ambiguous and should be avoided

The relationship of murine to epidemic typhus has been the subject of much speculation. One theory postulates that murine typhus is the more ancient disease as shown by the fact that the two principal hosts of *R. mooseri*, the rat and the rat flea, undergo no harmful effects from their intimate association with it By contrast, *R. prowazeki* causes a serious illness in man and a fatal infection in the louse. These facts have been taken as evidence that, from the evolutionary viewpoint, the association of man and human lice with typhus rickettsiae is relatively recent.

The Spotted-Fever Group

The spotted-fever group includes, in addition to Rocky Mountain spotted fever of the United States and Canada, apparently identical infections in Mexico (*Fiebre manchada, fiebre de choix* and *fiebre pinta*), Panama, Colombia (Tobiã fever), and Brazil (São Paulo and Minas Gerais fevers), as well as other tick- or mite-borne diseases such as tick-borne typhus (boutonneuse fever) of the Mediterranean regions of Europe and Africa, and the Crimea; identical or closely related tick-borne infections (tick-borne typhus, tick typhus or tick-bite fever) of all parts of Africa; Queensland tick typhus, rickettsialpox, maculatum disease, and the tick-borne rickettsioses of India (Indian tick typhus) and the Soviet Union (Siberian tick typhus)

ROCKY MOUNTAIN SPOTTED FEVER

(SYNONYMS Mountain fever, typhomalaria fever, Bull fever, black fever, blue disease, spotted fever and American spotted fever The author suggests "New World spotted fever")

INTRODUCTION

Rocky Mountain spotted fever is an acute, endemic, infectious disease which is recognized as being one of the severest of all infections (Rosenblum et al., 1952). Essentially, it is a generalized intracellular infection of the small peripheral blood vessels The causative agents are *Rickettsia rickettsii* (Bengtson, 1948), *Dermacentroxenus rickettsi*, Wolbach, 1919, *Rickettsia rickettsi* (Brumpt, 1927), *Rickettsia brasiliensis* (Monteiro, 1931), and *Rickettsia typhi* (do Amaral and Monteiro, 1932). The only known method of natural transmission to animals or man is through the medium of infected ticks

HISTORY

Rocky Mountain spotted fever was first reported from the Rocky Mountain region of Montana in 1873. In 1896, Wood gave a detailed account of the disease in Idaho This was followed by Maxey's report in 1899 which described the disease as "an acute, endemic, non-contagious but probably infectious, febrile disease, characterized clinically by a continuous moderately high fever, severe arthritic and muscular pains, and a profuse petechial or purpural eruption in the skin, appearing first on the ankles, wrists and forehead, but rapidly spreading to all parts of the body."

Wilson and Chowning, 1902, investigated the disease and claimed an erythrocytic parasite, *Piroplasma hominis*, was the causative agent. They also suggested that the disease was caused by the bite of the wood tick, *Dermacentor andersoni* In 1906a, Ricketts achieved the first transmission of the disease to experimental animals (guinea pigs and monkeys) by inoculation with infected human blood.

In the same year, Ricketts, 1906b, and King, 1906, independently reported that the

disease was transmitted by the wood tick,* and in the following year, Ricketts, *1907b*, demonstrated the occurrence of naturally infected ticks in the *Bitter Root Valley* of western Montana. In 1907c, Ricketts showed that the infectious agent, acquired by immature ticks at any stage, was carried through to the adults, and that at least a certain proportion of infected females transmitted the infection to their progeny through eggs. In 1909, Ricketts described the disease-producing micro-organism in smears prepared from the blood of man, monkey, guinea pig and from tissues of the wood tick. In 1910, Ricketts and Wilder, by cross-immunity experiments, showed that Rocky Mountain spotted fever and typhus fever are distinct and separate entities. In 1919, Wolbach reported the results of his careful etiologic and pathologic studies and named the etiologic organisms *Dermacentroxenus rickettsi*. Wolbach differentiated between this organism and nonpathogenic organisms in tick tissues and was the first to demonstrate the intranuclear multiplication of the rickettsiae in tick tissue. In *1923*, Parker reported the stage-to-stage transmission of the spotted fever rickettsiae in the life-cycle of both *Dermacentor andersoni* and *Haemaphysalis leporis-palustris*. In 1931 Rumreich et al recorded the occurrence of spotted fever in the eastern United States and in the same year Dyer and co-workers (1931) reported on the transmission of the infection by the dog tick *Dermacentor variabilis*.

Rocky Mountain spotted fever was first recognized in Brazil by Piza et al (1931), in Colombia by Patino et al (1937), in Canada by Hearle (*1938*) and Gibbons (1942), in Mexico by Bustamente and Varela (*1943*), and in Panama by De Rodaniche and Rodaniche (1950).

Clinical Picture

Rocky Mountain spotted fever is recognized as being one of the most severe of all infectious diseases. In many of its aspects, Rocky Mountain spotted fever resembles typhus, the chief differences being the duration of fever, the severity of the disease, and the time of appearance and the location of the rash. Attacks range from mild ambulatory and abortive forms to rapidly terminating fatal infections. The fatality rate varies in different regions and for different ages. In vaccinated persons and young children, the attacks are frequently mild and atypical.

In nonvaccinated adults, the incubation period of the disease is usually 4 to 8 days but may show extremes of 2 to 12 days. The prodromal manifestations are listlessness, malaise, headache, loss of appetite and chilling sensations. Onset of the disease is usually abrupt, coming as a rule in the late afternoon or early evening. It is manifested by a definite chill, pronounced headache, severe aches and pains in the muscles, bones and joints, profound prostration and a rapidly rising fever that continues to mount into the second week. Myalgia and arthralgia are marked, and in the more severe form, epistaxis may occur early.

As the disease progresses, mental confusion, restlessness, dulling of the senses and lethargy progressing to coma may be noted. Muscular twitching, fibrillary tremors, purposeless movements and abnormal neurologic signs may occur. Indeed, the picture may be that of an acute encephalitis. Fevers of 104° to 105° F. or higher are common. Remissions of 1° to 3° F. may be observed in morning temperatures. With recovery from the acute manifestations of illness the fever falls, either by rapid or slow lysis, usually at about the end of the 3rd week, although mild cases may become afebrile before the end of the 2nd week. Early in the disease the pulse is of good volume and slow, averaging approximately 90 beats per minute. One of the characteristics of spotted fever at its onset is the early disproportion of the pulse and temperature ratio. When myocardial weakening occurs in severe cases as a result of toxemia, loss of volume and strength of the pulse occurs. As a result of myocardial involvement and vascular collapse, the blood pressure falls, and the first heart sound becomes muffled and indistinct. The pulmonary edema which then appears often indicates a fatal termination within a few hours. The respirations are at

* Doctors McCalla and Brereton of Boise, Idaho (reported by Ricketts, 1907a), probably performed the first experiments to show that wood ticks could transmit the disease to human subjects. These doctors infected 2 individuals in series by the bite of a tick which they had removed from one of their patients. These experiments were not known to Ricketts, 1906b, or King, 1906, at the time they did their work, although the studies of McCalla and Brereton preceded theirs by more than a year.

HISTORY

Rocky Mountain spotted fever was first reported from the Rocky Mountain region of Montana in 1873. In 1896, Wood gave a detailed account of the disease in Idaho. This was followed by Maxey's report in 1899 which described the disease as "an acute, endemic, non-contagious but probably infectious, febrile disease, characterized clinically by a continuous moderately high fever, severe arthritic and muscular pains, and a profuse petechial or purpural eruption in the skin, appearing first on the ankles, wrists and forehead, but rapidly spreading to all parts of the body"

Wilson and Chowning, 1902, investigated the disease and claimed an erythrocytic parasite, *Piroplasma hominis*, was the causative agent They also suggested that the disease was caused by the bite of the wood tick, *Dermacentor andersoni* In 1906a, Ricketts achieved the first transmission of the disease to experimental animals (guinea pigs and monkeys) by inoculation with infected human blood

In the same year, Ricketts, 1906b, and King, 1906, independently reported that the

FIG 126. Typical rash on a patient suffering from Rocky Mountain spotted fever

ondary anemia The white cell count usually ranges between 12,000 and 15,000 per cu. mm , but may go as high as 30,000 Leukopenia, with white blood cell counts of 4,000 to 6,000, may be present at the onset of the disease, the differential count then shows a neutropenia The urine usually shows no abnormalities, although slight albuminuria may appear, apparently as the result of the fever, and then disappear with convalescence The cerebrospinal fluid may be under increased pressure, especially when generalized edema is present The protein content of the spinal fluid is usually normal An increase in mononuclear cells is often seen accompanying the encephalitis which [redacted] so common that it may be considered a part of the disease Nervous manifestations are quite common and include headache, restlessness, insomnia, confusion, disorientation, coma, convulsions, hyperactive and pathologic reflexes, cranial nerve palsies, paraplegia and hemiplegia In fulminating cases, coma usually precedes death, which occurs most often at the end of the 2nd week of illness

Rosenblum et al (1952) state that in some patients the acute changes clear up with convalescence, but that in others the residual damage persists for longer than a year and may be considered permanent Thirty-seven patients of all ages who had had spotted-fever infections from 1 to 8 years previously were re-examined by Rosenblum [redacted] al (1952) Twenty-one of the 37 patients showed some type of neurologic sequelae at the time of re-examination Fourteen showed a history of symptoms related to the central nervous system, 6 had neurologic signs, and 12 clearly showed abnormal electroencephalograms An additional 12 patients had borderline elec-

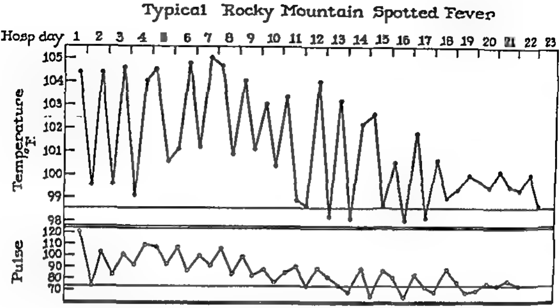

FIG 125 Temperature and pulse-rate curves of a typical case of Rocky Mountain spotted fever before the introduction of treatment by para-aminobenzoic acid and serum (Dr. R R Parker, Rocky Mountain Spotted Fever Laboratory, U. S Public Health Service, Hamilton, Mont)

first normal or but slightly increased. They accelerate, in severe cases, with alterations of the temperature and pulse ratio The increase in rates often indicates the development of pneumonia Terminal temperatures of 108° F, pulse rates of 140 to 160 and respiration rates of 40 to 60 are not uncommon (Baker, 1951). A short incubation period, high pulse rate, severe mental changes, edema, anuria or oliguria, a fine petechial rash and pneumonia are poor prognostic signs. Figure 125 shows temperature and pulse rate curves of a typical untreated case of Rocky Mountain spotted fever.

A distinctive rash usually appears on the 2nd to the 4th day of the disease but may be delayed until the 5th or 6th day. It may resemble the slight mottling seen in early measles The rash first appears on the ankles and the wrists and spreads rapidly to the legs, the arms and the chest The lesions are macular at first but later become maculopapular. Definite petechiae may form. The lesions are more pronounced on the extremities. The palms and the soles and at times even the face and the scalp become involved. Early in the course of the disease, the spots are less pronounced during the morning remissions of fever but progressively become more distinct each day until they are definitely petechial in all but the mildest types of infection (Fig 126). Extension of the rash usually becomes complete within 2 to 3 days so that the entire body is covered. The lesions of Rocky Mountain spotted fever do not disappear on pressure except during the early stages of the disease and can be accentuated by tourniquet application. In severe cases, the lesions become confluent, deep red or purplish in color and often necrotic. Masses of such areas may involve the entire body. The afflicted individual presents a most tragic picture if terminal gangrene develops with sloughing of dependent body parts. The eruption gradually fades as patients recover, with the process taking much longer, the more severe the disease There may be branny desquamation Pigmentation remains at the site of former eruptions For several months following recovery, overexposure to heat or cold often brings out temporary recurrence of the lesions. These have no significance and clear within a few minutes after the skin temperatures return to normal

The blood findings in Rocky Mountain spotted fever are not significant There is a lowered red blood cell count and hemoglobin content later in the disease resulting in a sec-

Mexico and Brazil Animals serving as hosts to *D andersoni* and believed to be responsible for maintaining the infection in nature are the tree squirrel, ground squirrel, snowshoe rabbit, jack rabbits (including the black-tailed jack rabbit), cottontail rabbit, porcupine, chipmunk, pack rat, wood rat, meadow mouse, deer mouse, weasel, marmot and dog It may be significant, as pointed out by Jellison (1945), that in the United States a close geographic relationship exists between spotted fever and a species of cottontail rabbit, *Sylvilagus nuttali* Parker (1938) likewise has emphasized his belief of the importance in nature of the rabbit-tick-rabbit host association in carrying at least low-grade strains of infection Most of the natural hosts show only inapparent infections, with no diagnostic gross lesions or distinctive febrile reactions, and seldom die Recently, Gould and Miesse (1954) reported the isolation of a strain of rickettsiae belonging to the spotted fever group from the tissues of a meadow mouse, *Microtus pennsylvanicus* (an apparently healthy male), collected during a survey (1952-1953) in a suburb of Alexandria, Va This is the first time that a spotted fever strain of rickettsiae has been definitely recovered from naturally infected animals collected within the United States This agent, which was found to be a mild strain, showed an incubation period of 2 to 8 days and a febrile phase of 5 to 9 days duration for inoculated guinea pigs but was not lethal No scrotal reactions were produced in early passages in guinea pigs, but in later passages some animals developed swelling and erythema of the scrotum The strain was lethal for chick embryos 4 to 6 days following inoculation

Parker et al (1951) reported that the sera from 8 of 10 snowshoe rabbits that were trapped and brought to the laboratory were positive for spotted fever by the complement-fixation test, and *Haemaphysalis leporis-palustris* (H-l-p) ticks picked from 3 of the rabbits that showed a positive serologic reaction were shown to contain rickettsiae of the spotted-fever type Likewise, Philip and Hughes (1953) reported that the sera of 8 of 127 black-tailed jack rabbits (*Lepus californicus deserticola*) collected in Nevada in 1951, and 27 of 133 similar sera collected in 1952, were positive for spotted-fever type rickettsiae by the complement-fixation test. In addition, certain of the sera obtained in 1952 that showed positive complement-fixation reactions against spotted-fever antigen were subjected to toxin-neutralization tests in mice (cf. Bell and Pickens, 1953) Four of 8 sera were also positive by this test in serum dilutions between 1 8 and 1 64 Of 5 other sera, which were negative in complement-fixation tests, 2 showed positive neutralization titers of 1 16 and 1 32, respectively (Philip et al, 1955) These data, of course, indicate that rabbits other than cottontails are of importance in the spotted fever problem In Brazil, the opossum (*Didelphus paraguayensis* and *D aurita* in São Paulo, and *D marsupialus* in Minas Gerais) has been found naturally infected (Travassos, 1948) Magalhães and Rocha (1942) not only found dogs susceptible to experimental infection with Brazilian spotted fever, but also found them naturally infected Travassos (1948) inoculated guinea pigs with blood from an apparently normal dog that lived in a spotted fever endemic area and found the guinea pigs to be subsequently immune to spotted fever challenge Experimentally, the dog and the opossum (*D aurita*) develop inapparent infections with the São Paulo strain, and viable rickettsiae persist in these hosts for long periods of time Six serial passages of the São Paulo strain through opossums (*D aurita*) resulted in a loss of virulence of the agent The Brazilian cavy (*Cavia aperea*), the wild rabbit (*Sylvilagus minensis*), the domestic dog and the opossum (cited above) have all been shown to be naturally infected, the Brazilian plains dog, capybara (*Hydrochoerus capybara*), coati and certain kinds of bats are susceptible (Dias and Martins, 1939) In Colombia, Patiño-Camargo (1941) showed the native monkey, *Cebus fatuelles*, to be susceptible

Most large domestic animals are insusceptible However, Badger (1933) found dogs and sheep mildly susceptible to experimental infection Older dogs showed no clinical manifestations, although rickettsiae were recovered from their blood on the 4th, the 6th and the 8th days following inoculation A grown dog, reared in an endemic spotted-fever area, was apparently immune. A puppy reacted to experimental inoculation with fe-

troencephalographic abnormalities Abnormal electroencephalograms were seen in a high proportion of patients who had fever for more than 10 days. Berlin and Thomas (1948) likewise have reported that occasional patients may show permanent severe neurologic sequelae eventually resulting in death Even in mild cases, convalescence is slow, and complete recovery from severe infection may require several months to a year or longer.

Harrell (1949), in his excellent review, mentioned that myocardial failure may result from the pathologic process or from overloading the circulation by intravenous therapy Along these lines, Aquilina et al. (1952) have reported what may be the first case of Rocky Mountain spotted fever complicated by an intermittent nodal tachycardia. This condition is apparently associated with extensive myocardial damage It is generally considered that persons having recovered from spotted fever are permanently immune.

Pathologic Picture

[illegible]

2nd week after infection The spotted fever rickettsiae can be demonstrated fairly readily in sections, and their localization determines the sites of lesions (Wolbach, 1948). The rickettsiae first invade the nuclei of capillary endothelial cells, where they multiply in great numbers and destroy the cells The lesion then extends centripetally along the intima into slightly larger vessels (arterioles), where smooth muscle cells of the media are also invaded and destroyed (Lillie, 1941) The destruction of smooth muscle cells is a most distinctive feature of Rocky Mountain spotted fever With the death of the cells, necrosis occurs in the intima and the media of the blood vessels, causing thrombosis and extravasation of blood. Microinfarcts are then formed, chiefly in the skin, the subcutaneous tissues and the central nervous system. As the disease develops, perivascular accumulations of mononuclear macrophages appear, and the vascular lesions assume a proliferative or granulomatous character. According to Wolbach (1948), "the necrosis of skin in Rocky Mountain spotted fever occurs independently of stasis produced by pressure. Its common sites are scrotum, prepuce, fingers, toes and ear lobes; rarely, the soft palate." In the central nervous system, areas of demyelination may be found adjacent to or removed from the vascular lesions. Rocky Mountain spotted fever without question produces greater damage to the skin, the subcutaneous tissues and the brain than does any other rickettsial disease. Lillie has reported (1941) that the pathologic picture of spotted fever in the Rocky Mountain area and in the eastern United States is essentially the same

One feature of spotted fever, which cannot be emphasized too strongly, is that it may be duplicated exactly in experimental animals, Wolbach, 1919. Guinea pigs sacrificed for examination at the height of the infection show edema and hemorrhages in the skin and the subcutaneous tissues of the scrotum, the paws and the ears. Inguinal and axillary lymph nodes are swollen and reddened The spleen ranges from 3 to 5 times larger than normal and is dark red and firm in consistency; occasionally, there is a very thin, translucent layer of fibrin upon its surface The most striking changes are found in the testes and the adnexa. The former are swollen and markedly injected, usually with minute hemorrhages in the tunica at both poles Small hemorrhages are also found in the polar fat, the epididymus, in the subcutaneous tissues surrounding the anus and the scrotum and often in the cremasteric muscles and the parietal tunicae, which are deep red and adherent, not only to each other but to the testes Later in the course of the disease, the testes become adherent to the scrotum, and the skin of the scrotum, the paws and the ears frequently shows necrosis The central nervous system may be injected but shows no gross lesions. The histologic character of individual lesions in the brain does not differ appreciably from those caused by typhus except that, in spotted fever, a higher proportion of the focal lesions are found in the pons, the medulla, the midbrain and the cerebellum.

Experimental Infection; Host Range

Man is entirely an incidental victim to spotted fever and is in no way responsible for the maintenance of the infection in nature, which is largely due to ticks and the animals on which they feed. The epidemiologic evidence in North America clearly points to certain small animals belonging to the many groups of rodents which serve as hosts to the immature stages of the tick vectors Dogs also are involved in the eastern United States,

ring in pairs and often surrounded by a very narrow but definite clear zone, or halo, as if encapsulated. The distal ends of the pairs are often tapered, so that they resemble minute pneumococci The rickettsiae average about 1 μ in length and from 0 2 to 0 3 μ in width They stain best by special methods with Giemsa stain, the rickettsiae take a purplish tinge; with the Castaneda method they have a light blue appearance, whereas with the Macchiavello method,* a most satisfactory stain for rickettsiae, they are stained a bright pink or red against a bluish background

Figure 128 shows spotted fever rickettsiae in a stained smear of infected yolk sac material. Like other rickettsiae, *R. rickettsii* is gram negative All attempts to cultivate *R rickettsii* on artificial or cell-free media have been unsuccessful, but they grow readily in tissue cultures and in the chorio-allantois and the yolk sac of the developing chick embryo (Cox, 1938, 1941, 1948) The rickettsiae of the spotted fever group (*R rickettsii* and *R conorii*), in contrast with the typhus rickettsiae (*R. typhi* and *R. prowazekii*), continue to grow in the chorio-allantoic membrane and the yolk sac of eggs placed at room temperature for 2 or 3 days after the death of the embryo A similar observation has been reported by Bell and Pickens (1953) in their studies on a toxic substance associated with spotted fever rickettsiae The striking feature of *R rickettsii* in tick tissues and plasma tissue cultures is its apparent preference for the cell nuclei where it grows in compact clusters (Pinkerton and Hass, 1932) Often the entire nucleus becomes distended with organisms There is a definite peripheral conden-

* Macchiavello's stain Fix slide in flame Flood smear with 0 5 per cent solution of aqueous basic fuchsin of pH 7.2 to 7 5 Stain for 5 minutes Rinse rapidly with 0 5 per cent citric acid solution Wash thoroughly with tap water Counterstain with 1.0 per cent aqueous methylene blue for 1 or 2 minutes Rinse well with tap water and examine when dry

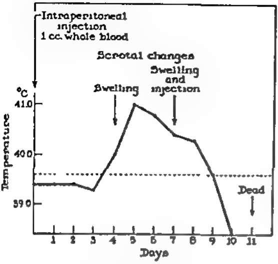

FIG. 127 Temperature curve of a guinea pig infected with the Bitter Root strain of Rocky Mountain spotted fever.

ver and respiratory symptoms, and rickettsiae were recovered from its blood on the 4th day. Infected *D andersoni* were fed on 2 puppies which, after incubation periods of 5 and 6 days respectively, developed signs of illness, and rickettsiae were recovered from the blood of each Rickettsiae were recovered from the blood of a young sheep on the 4th, the 6th, the 8th and the 10th days after inoculation Miller (1950) was unable to induce apparent infection in 6 foxes and 2 raccoons by inoculating them with a highly virulent strain of rickettsiae; however, the animals developed complement-fixing antibodies. Dogs, foxes and raccoons, on which *D. variabilis* nymphs and adults were found under natural conditions on Long Island, N. Y., showed high titers for spotted fever complement-fixing antibodies.

The guinea pig is the most suitable common laboratory animal for experimental purposes The guinea pig's temperature usually does not rise until 3 or more days have passed after the inoculation of blood from human patients, and generally a few guinea pig passages are required before the incubation period becomes fixed at 2 or 3 days (Fig 127). The febrile period may last from 5 to 14 days Death, which usually occurs with well-established strains on the 6th to the 8th day of fever, is preceded by a sudden drop in temperature to subnormal. If a guinea pig recovers, its temperature begins to drop at the end of 7 or 8 days and gradually reaches normal within 3 to [illegible] days The first sign of the disease in male guinea pigs is swelling and reddening of the scrotal skin on the 3rd or the 4th day of fever (Fig 127). At this time, the animal shows signs of discomfort, loss of appetite and roughening of the coat. The scrotal reaction may develop into a necrotic condition, followed by sloughing and subsequent healing with scar formation. Necrosis and sloughing of the ears and the foot pads also occur frequently. Rabbits rarely die of the disease, although they develop fever and may show ear and scrotal reactions similar to those seen in guinea pigs. Rabbits develop antibodies detectable by the Weil-Felix reaction. The course of the disease in monkeys may be very rapid, with early death occurring with highly virulent strains. Monkeys frequently develop a rash on the face, over the lower back and on the thighs. Swelling and redness of the scrotum is common Necrosis of the ears also occurs Like rabbits, monkeys develop antibodies detectable by the Weil-Felix reaction. White rats are moderately susceptible to infection. In tests carried out in a series of white rats, white mice and ground squirrels to determine the persistence of spotted-fever infection, the only definitely positive test was obtained with the brain of a white rat sacrificed 30 days after intraperitoneal inoculation (Philip and Parker, 1938). No definite positive result was obtained in any of similar tests carried out to determine the persistence of tick-borne typhus. Concerning persistence of infection in man, it is worthy of note that Parker et al. (1954) recovered viable rickettsiae from the lymphatic tissues of a colored male 1 year following his recovery from Rocky Mountain spotted fever. Even more remarkable is the fact that the recovery was made from the lymph node tissue after it had been stored for 29 months in a dry-ice chest.

Etiology

The distribution and the morphology of *R. rickettsii* are identical in the tissues of man, monkey, rabbit and guinea pig, Wolbach, 1919. In tissue sections, the rickettsiae appear as minute organisms, frequently occur-

to interfere with the virulent rickettsiae The most protective material produced by various fractionation procedures contained protein, lipid, carbohydrate, less than 0 1 per cent phosphorus, no pentosenucleic acid and no deoxyribosenucleic acid The rickettsial interfering substance is highly specific, the interference phenomenon is apparently independent of the time that the challenge dose is given, provided that it follows the protective dose by no longer than approximately 10 days

Diagnosis

In spite of the commonly expressed opinion that spotted fever is an easily recognized infection, even those familiar with the disease may make errors in diagnosis The very mild infections and the rapidly fulminating types are quite difficult to diagnose clinically Furthermore, in areas where both spotted fever and murine (endemic) typhus are present, an additional difficulty is encountered because of their marked clinical similarity Rocky Mountain spotted fever should be suspected in cases of febrile disease that occur during the tick season in those persons whose occupations or habits expose them to ticks Close examination may show the presence of a tick or an indurated area representing the site of a tick-bite The differential diagnosis is difficult, since it entails consideration of certain exanthematous diseases, as well as other rickettsial diseases and tick-borne infections Rocky Mountain spotted fever rash may resemble that of measles, meningococcal meningitis, scarlet fever, smallpox, typhoid fever and septicemic conditions as well as certain drug rashes Measles is the disease most frequently confused with spotted fever

In the United States, the other rickettsial diseases likely to cause difficulty in diagnosis are rickettsialpox and murine typhus Rickettsialpox (see below), transmitted to man by means of a mite, has been found thus far only in urban areas of the east and is characterized by an initial lesion (eschar) at the site of the mite-bite Murine typhus is transmitted to man by a flea-bite It occurs mainly in the late summer and fall in the southern and south-eastern states and is characterized by the development of a rash, first on the trunk and later on the extremities The rash in murine typhus is usually much less noticeable and of shorter duration than that of spotted fever The two tick-borne diseases which must be considered are Colorado tick fever and tularemia There is usually no rash during Colorado tick fever The development of an ulcer at the site of tick attachment, accompanied by enlargement of the regional lymph nodes, suggests tularemia

The infection test, the Weil-Felix reaction, the protection or virus neutralization test and the complement-fixation test are ordinarily used for diagnosis In addition, a toxic substance (Bell and Pickens, 1953) and serologically active *erythrocyte-sensitizing* substances (ESS) have been demonstrated (Chang et al, 1954) for several members of the spotted-fever group of organisms Both of these findings are important because they have not only increased our knowledge about certain basic properties of the organisms, but because they could well be put to practical use for diagnostic purposes

In the infection test, male guinea pigs are inoculated intraperitoneally with blood from a suspected patient Clotted blood, plasma, serum or, preferably, whole citrated blood may be used Once the disease is established, it may be maintained by inoculating normal male guinea pigs intraperitoneally with blood, splenic tissue or testicular washings taken from an infected guinea pig on the 2nd or the 3rd day of fever By establishing the disease in guinea pigs, it is possible to apply cross-immunity tests with known strains of spotted fever rickettsiae or other infectious agents

The Weil-Felix reaction, which consists of testing a patient's serum for agglutinins against Proteus organisms, aids in limiting the probable diagnosis to the rickettsial group of diseases, but it is of no certain aid in differentiating spotted fever from typhus In using the Weil-Felix test, it is desirable that at least 2 blood samples be used one taken as soon as spotted fever is suspected, the other approximately 2 weeks after the onset The first blood sample is seldom diagnostic and is valuable chiefly as a reference point in determining whether there is a subsequent rise in titer in the second specimen A titer of less than 1 320 cannot be considered definitely diagnostic In the majority of spotted-fever cases the titers for OX-19 agglutinins are highest, but occasionally, particularly with sera from patients in certain areas of Wyoming (Parker, 1938), those for

sation of the nuclear chromatin, similar to that seen in association with the intranuclear inclusions of certain virus diseases. The unique intranuclear localization of *R. rickettsii* was used by Pinkerton (1936) in the classification of atypical strains which gave ambiguous cross-immunity reactions Spotted fever rickettsiae do not pass Berkefeld V, N or W candles or Seitz filter pads They are killed in a few minutes by exposure to moist heat at 50° C or to chemical agents, and in a few hours by desiccation at room temperature Red and white blood cells from infected guinea-pig blood retain their infectivity even after repeated washings At room temperature guinea pig blood retains its infectivity for only about a week, but in a cold room it remains infectious for about 2 weeks Infected guinea pig brain and spleen, suspended in glycerol stored in sealed containers at −70° C or in a dry-ice box, remain infectious for periods up to a year

In 1953, Price reported his observations on an interference phenomenon which was observed for the first time with rickettsial infections He used two strains of Rocky Mountain spotted fever one of low virulence (T strain) and one of high virulence (R strain). Both strains were shown to possess toxin (cf. Bell and Pickens, 1953), a hemolytic factor, and to be practically identical immunologically. It was found that the avirulent T strain protected guinea pigs when both strains were given simultaneously, or when the R strain was given as much as 14 days later, it interfered with the R strain when the T strain had been inactivated by ultraviolet irradiation but not by heat; and it protected animals against tick-borne typhus. The protective property was shown to be a part of the rickettsiae and not some other substance present in the infected yolk sac suspensions. Suspensions of rickettsiae causing Q fever, scrub typhus, epidemic and murine typhus which are immunologically unrelated to Rocky Mountain spotted fever likewise were found to protect guinea pigs against an injection of the virulent R strain of spotted fever. However, the inoculated animals did develop the typical symptoms caused by the different rickettsiae used to protect them against spotted fever, but the spotted fever rickettsiae found in the testes-tunica tissues were stated to be at least 1,000 times fewer than those found in control animals. In another interesting experiment, ground squirrels, field mice (*Microtus*) and cottontail rabbits were infected by exposure to many *D. andersoni* containing a mildly virulent strain of spotted fever and a few *D. andersoni* containing a highly virulent spotted fever strain. Uninfected ticks allowed to feed upon these animals were found to contain only the mildly virulent strain This experimental finding may help to explain some of the interesting epidemiologic observations that, in certain localized areas, Rocky Mountain spotted fever strains having either high or low virulence persist in ticks year after year.

In a subsequent paper, Price et al (1954) presented data indicating that the rickettsial-interference phenomenon is not due to competition between the rickettsiae for the same susceptible host cells. Guinea pigs injected intraperitoneally with highly virulent rickettsiae of the R strain of spotted fever, concentrated and inactivated with ultraviolet light, were found to be protected when challenged 3 hours later with highly virulent rickettsiae of the same strain The protection seemed to be dependent on the ratio of interfering dose to infecting dose and not on the number of susceptible host cells Thus, injections of 10^6 ultraviolet inactivated rickettsiae gave no protection to guinea pigs even when the challenge dose was only 100 living virulent rickettsiae However, 10^7 ultraviolet inactivated rickettsiae did confer some protection against as many as 10,000 challenge doses If the living, virulent rickettsiae were given 3 hours before the inactivated rickettsiae, little, if any, protection was observed in any case A chemical component was isolated from suspensions of the virulent R strain of rickettsiae by a procedure that involved purification by the celite and albumin process, and treatment in a sonic vibrator for 30 minutes. It caused no detectable symptoms of illness and was found to protect from 80 to 90 per cent of guinea pigs against a challenge of virulent rickettsiae given 3 hours later. Rickettsial suspensions that were prepared in a similar manner but without sonic vibration treatment showed no interference or protective effect. Concentrated preparations of the soluble antigen of *R. rickettsii* had no ability

to interfere with the virulent rickettsiae. The most protective material produced by various fractionation procedures contained protein, lipid, carbohydrate, less than 0.1 per cent phosphorus, no pentosenucleic acid and no deoxyribosenucleic acid. The rickettsial interfering substance is highly specific; the interference phenomenon is apparently independent of the time that the challenge dose is given, provided that it follows the protective dose by no longer than approximately 10 days.

Diagnosis

In spite of the commonly expressed opinion that spotted fever is an easily recognized infection, even those familiar with the disease may make errors in diagnosis. The very mild infections and the rapidly fulminating types are quite difficult to diagnose clinically. Furthermore, in areas where both spotted fever and murine (endemic) typhus are present, an additional difficulty is encountered because of their marked clinical similarity. Rocky Mountain spotted fever should be suspected in cases of febrile disease that occur during the tick season in those persons whose occupations or habits expose them to ticks. Close examination may show the presence of a tick or an indurated area representing the site of a tick-bite. The differential diagnosis is difficult, since it entails consideration of certain exanthematous diseases, as well as other rickettsial diseases and tick-borne infections. Rocky Mountain spotted fever rash may resemble that of measles, meningococcal meningitis, scarlet fever, smallpox, typhoid fever and septicemic conditions as well as certain drug rashes. Measles is the disease most frequently confused with spotted fever.

In the United States, the other rickettsial diseases likely to cause difficulty in diagnosis are rickettsialpox and murine typhus. Rickettsialpox (see below), transmitted to man by means of a mite, has been found thus far only in urban areas of the east and is characterized by an initial lesion (eschar) at the site of the mite-bite. Murine typhus is transmitted to man by a flea-bite. It occurs mainly in the late summer and fall in the southern and south-eastern states and is characterized by the development of a rash, first on the trunk and later on the extremities. The rash in murine typhus is usually much less noticeable and of shorter duration than that of spotted fever. The two tick-borne diseases which must be considered are Colorado tick fever and tularemia. There is usually no rash during Colorado tick fever. The development of an ulcer at the site of tick attachment, accompanied by enlargement of the regional lymph nodes, suggests tularemia.

The infection test, the Weil-Felix reaction, the protection or virus neutralization test and the complement-fixation test are ordinarily used for diagnosis. In addition, a toxic substance (Bell and Pickens, 1953) and serologically active erythrocyte-sensitizing substances (ESS) have been demonstrated (Chang et al., 1954) for several members of the spotted-fever group of organisms. Both of these findings are important because they have not only increased our knowledge about certain basic properties of the organisms, but because they could well be put to practical use for diagnostic purposes.

In the infection test, male guinea pigs are inoculated intraperitoneally with blood from a suspected patient. Clotted blood, plasma, serum or, preferably, whole citrated blood may be used. Once the disease is established, it may be maintained by inoculating normal male guinea pigs intraperitoneally with blood, splenic tissue or testicular washings taken from an infected guinea pig on the 2nd or the 3rd day of fever. By establishing the disease in guinea pigs, it is possible to apply cross-immunity tests with known strains of spotted fever rickettsiae or other infectious agents.

The Weil-Felix reaction, which consists of testing a patient's serum for agglutinins against Proteus organisms, aids in limiting the probable diagnosis to the rickettsial group of diseases, but it is of no certain aid in differentiating spotted fever from typhus. In using the Weil-Felix test, it is desirable that at least 2 blood samples be used: one taken as soon as spotted fever is suspected, the other approximately 2 weeks after the onset. The first blood sample is seldom diagnostic and is valuable chiefly as a reference point in determining whether there is a subsequent rise in titer in the second specimen. A titer of less than 1:320 cannot be considered definitely diagnostic. In the majority of spotted-fever cases the titers for OX-19 agglutinins are highest, but occasionally, particularly with sera from patients in certain areas of Wyoming (Parker, 1938), those for

OX-2 agglutinins are highest. The Proteus agglutinins usually appear toward the end of the 2nd week of the disease, but sometimes they do not appear until early convalescence; in some patients, no Proteus agglutinins are produced.

According to Parker (1938), the protection or virus-neutralization test is nearly always of diagnostic value. As performed in his laboratory, duplicate mixtures are prepared, each containing 0.5 cc. of serum and 0.1 cc., 0.25 cc. and [illegible]5 cc. of serum virus, respectively. The mixtures are held at room temperature for 30 minutes and then injected intraperitoneally into guinea pigs. Control animals receive the same amount of infectious serum mixed with normal serum. The most consistent results are obtained with blood samples taken in convalescence, although some sera taken during lysis of the disease show definite neutralizing capacity. The neutralization test is claimed to be of greater value than the agglutination reaction in testing blood specimens from relatively mild cases and may give even better results than the infection test

The complement-fixation test is an additional laboratory aid and has the distinct advantage over the Weil-Felix reaction that it may be made highly specific and used to differentiate Rocky Mountain spotted fever from epidemic typhus, murine typhus, Q fever and scrub typhus as well as other members of the spotted-fever group. Satisfactory antigens may be prepared from rickettsiae cultivated by the agar-tissue culture method of Zinsser, et al. (1939) or by the yolk-sac method of Cox (1938) Spotted-fever and tick-borne typhus rickettsiae contain soluble [illegible]

removed, by subjecting the rickettsiae to repeated washings, and the resulting washed rickettsiae provide highly specific antigens (Plotz et al., 1944). Plotz (1945), using purified antigens prepared from rickettsiae of Rocky Mountain spotted fever, boutonneuse fever, South African tick-bite fever and Bra- [illegible]

identical and that boutonneuse and South African tick-bite fever (both now included in tick-borne typhus) are antigenically related. There was no reciprocal cross-fixation, however, between Rocky Mountain or Brazilian spotted fever and boutonneuse or South African tick-bite fever. Pereira and Travassos (1951) likewise have reported the rickettsiae of Rocky Mountain spotted fever and Brazilian spotted fever (São Paulo typhus) to be antigenically identical by using complement-fixation tests with washed rickettsial suspensions. Silva-Goytia and Elizondo (1952), using [illegible] tity b[illegible] strai[illegible] spotted fever strains (Michoacan and La Laguna strains I and II). The latter workers support the suggestion of Bustamente and Varela (1943) that the several colloquial names for spotted fever infections in various parts of the western hemisphere be combined under the term, American spotted fever. Since the word "American" is considered in many quarters of the world to pertain to the United States of America, the author suggests that perhaps a more appropriate and realistic term would be "Western Hemisphere" or "New World" spotted fever.

Van der Scheer et al. (1947) prepared purified soluble antigens from spotted-fever [illegible]

procedures commonly used in performing complement-fixation tests. They found the modified Kolmer test used by Van der Scheer et al (1947) to possess the advantages of being specific, sensitive and already essentially familiar to workers in most public health laboratories.

The Weil-Felix reaction and the protection test are of no value in testing for long-past infections. The agglutinin titer for Proteus strains falls rapidly after recovery is complete, and it is unusual for a patient's serum to show neutralizing capacity [illegible] year after illness However, complement-fixing antibodies usually appear during the 2nd week of illness and persist for at least 6 to 8 years Some comment should be made at this point, however, about the effect of antibiotic therapy upon the development of specific, rickettsial complement-fixing antibodies. Wong and Cox (1948) found that chlortetracycline, administered to guinea pigs at very early stages of experimental rickettsial infections, completely suppressed the production of complement-fixing antibodies. Harrell (1949) likewise indicated that the administration of chlortetracycline or chloramphenicol to man during the

early stages of illness interfered with the development of complement-fixing antibodies to Rocky Mountain spotted fever Schubert (1952) reviewed the literature dealing with this subject and pointed out that therapy with chlortetracycline or chloramphenicol apparently had less effect upon the development of Proteus agglutinins than upon the production of complement-fixing antibodies Lackman and Gerloff (1953) confirmed the fact that caution must be exerted in interpreting negative findings in complement-fixation tests in cases of Rocky Mountain spotted or typhus fever when the patient has been treated with chlortetracycline or chloramphenicol The Weil-Felix test appears to be of most value in such cases

In 1953, Bell and Pickens reported the occurrence in infected yolk sacs of specific toxic substances lethal for mice, associated with 10 strains of spotted-fever group rickettsiae including the agents of Rocky Mountain spotted fever (2 western Montana strains, a Minnesota and an Iowa strain), Brazilian spotted fever, boutonneuse fever South African tick-bite fever, Indian tick typhus and 2 strains of spotted-fever rickettsiae isolated from ticks, *A maculatum* and *H leporis-palustris*, respectively Attempts to demonstrate a toxin for *R. akari* (rickettsialpox) and *R australis* (Queensland tick typhus) were unsuccessful Toxin was neutralized in relatively high titer by sera from human beings and guinea pigs convalescent from spotted fever but not neutralized by sera from normal humans or guinea pigs or by sera from guinea pigs previously infected with epidemic typhus, murine typhus or Q fever The toxin produced by *R rickettsii* was found to be neutralized also by the sera of human beings and guinea pigs that had been vaccinated with spotted-fever tick vaccine This is a most interesting finding, since no satisfactory test for measuring the response of individuals to vaccination had been recognized previously, complement-fixation tests on such individuals thus far have always given inconclusive results Preliminary tests have also indicated that the toxin neutralization test can differentiate between the rickettsiae of Rocky Mountain spotted fever and of tick-borne typhus (boutonneuse fever) This finding suggests the possibility that the toxin neutralization test may be of value also in distinguishing between even more closely related strains of rickettsiae within the spotted fever group which differ from *R rickettsii* with respect to virulence or host species, e g., those strains isolated from *H leporis-palustris*, *D parumapertus* and *A maculatum*. While it has been shown that the complement-fixation test serves to differentiate between certain strains of spotted-fever rickettsiae, it has failed to do so between others (Parker et al , 1939) Certainly, the interesting possibilities promised by the toxin-neutralization test should be pursued to the fullest extent in order to elucidate further our knowledge concerning this most interesting group of organisms

In 1954, Chang et al reported that serologically active erythrocyte-sensitizing substances (ESS) were isolated from yolk-sac membranes infected with several rickettsiae of the Rocky Mountain spotted-fever group Long Island and R strains of Rocky Mountain spotted fever, the MK strain of rickettsialpox a North African strain of tick-borne typhus (boutonneuse fever) and a strain of South African tick-bite fever (also tick-borne typhus) Preliminary tests made with Queensland tick typhus failed to show ESS, but the tests were not conclusive Tests with immune sera indicated that the ESS obtained from all the above rickettsial strains were probably common and group specific Thus, sera from rickettsialpox and Rocky Mountain spotted fever patients agglutinated erythrocytes treated with rickettsialpox-ESS, Rocky Mountain spotted fever-ESS and boutonneuse fever-ESS to approximately the same titer. Human postvaccination sera gave weakly positive or negative tests Most rabbit convalescent sera agglutinated erythrocytes treated with rickettsialpox-ESS, Rocky Mountain spotted fever-ESS and boutonneuse fever-ESS Convalescent guinea pig sera gave irregular results. The ESS test, which appears to be somewhat more sensitive and simpler than the complement-fixation test, compared favorably with the complement-fixation and the Weil-Felix tests in the detection of early antibodies in studying 20 cases of Rocky Mountain spotted fever and 5 cases of rickettsialpox. ESS preparations made from yolk sacs infected with rickettsialpox were found to be stable at 4° C. for at least 1 year. Oc-

OX-2 agglutinins are highest. The Proteus agglutinins usually appear toward the end of the 2nd week of the disease, but sometimes they do not appear until early convalescence; in some patients, no Proteus agglutinins are produced.

According to Parker (1938), the protection or virus-neutralization test is nearly always of diagnostic value. As performed in his laboratory, duplicate mixtures are prepared, each containing 0.5 cc. of serum and 0.1 cc., 0.25 cc. and 0.5 cc. of serum virus, respectively. The mixtures are held at room temperature for 30 minutes and then injected intraperitoneally into guinea pigs. Control animals receive the same amount of infectious serum mixed with normal serum. The most consistent results are obtained with blood samples taken in convalescence, although some sera taken during lysis of the disease show definite neutralizing capacity. The neutralization test is claimed to be of greater value than the agglutination reaction in testing blood specimens from relatively mild cases and may give even better results than the infection test.

The complement-fixation test is an additional laboratory aid and has the distinct advantage over the Weil-Felix reaction that it may be made highly specific and used to differentiate Rocky Mountain spotted fever from epidemic typhus, murine typhus, Q fever and scrub typhus as well as other members of the spotted-fever group. Satisfactory antigens may be prepared from rickettsiae cultivated by the agar-tissue culture method of Zinsser, et al. (1939) or by the yolk-sac method of Cox (1938). Spotted-fever and tick-borne typhus rickettsiae contain soluble antigens which give cross-fixation respectively with tick-borne typhus or spotted-fever antisera. However, the soluble antigens may be removed, by subjecting the rickettsiae to repeated washings, and the resulting washed rickettsiae provide highly specific antigens (Plotz et al., 1944). Plotz (1945), using purified antigens prepared from rickettsiae of Rocky Mountain spotted fever, boutonneuse fever, South African tick-bite fever and Bra-

There was no reciprocal cross-fixation, however, between Rocky Mountain or Brazilian spotted fever and boutonneuse or South African tick-bite fever. Pereira and Travassos (1951) likewise have reported the rickettsiae of Rocky Mountain spotted fever and Brazilian spotted fever (São Paulo typhus) to be antigenically identical by using complement-fixation tests with washed rickettsial suspensions. Silva-Goytia and Elizondo (1952), using similar methods, showed complete identity between a Rocky Mountain spotted fever strain (Bitter Root Valley) and 3 Mexican spotted fever strains (Michoacan and La Laguna strains I and II). The latter workers support the suggestion of Bustamente and Varela (1943) that the several colloquial names for spotted fever infections in various parts of the western hemisphere be combined under the term, American spotted fever. Since the word "American" is considered in many quarters of the world to pertain to the United States of America, the author suggests that perhaps a more appropriate and realistic term would be "Western Hemisphere" or "New World" spotted fever.

Van der Scheer et al. (1947) prepared purified soluble antigens from spotted-fever rickettsiae which were highly specific and gave little or no fixation with syphilitic human sera. Schubert et al. (1951) compared 5 procedures commonly used in performing complement-fixation tests. They found the modified Kolmer test used by Van der Scheer et al. (1947) to possess the advantages of being specific, sensitive and already essentially familiar to workers in most public health laboratories.

The Weil-Felix reaction and the protection test are of no value in testing for long-past infections. The agglutinin titer for Proteus strains falls rapidly after recovery is complete, and it is unusual for a patient's serum to show neutralizing capacity a year after illness. However, complement-fixing antibodies usually appear during the 2nd week of illness and persist for at least 6 to 8 years. Some comment should be made at this point, however, about the effect of antibiotic therapy upon the development of specific, rickettsial complement-fixing antibodies. Wong and Cox (1948) found that chlortetracycline, administered to guinea pigs at very early stages of experimental rickettsial infections, completely suppressed the production of complement-fixing antibodies. Harrell (1949) likewise indicated that the administration of chlortetracycline or chloramphenicol to man during the

ally become afebrile within 48 to 72 hours after initiation of therapy, so that it can be discontinued after 4 to 6 days However, if a relapse occurs, another course of antibiotics may be given, since there is no evidence that the rickettsiae develop drug resistance Recently, reports have appeared indicating that a combination of specific antibiotic therapy with supportive hormone therapy (cortisone), gives promise of modifying further the severe effects of Rocky Mountain spotted fever as well as shortening its course (Aikawa and Harrell, 1953).

Arney (1952) treated a comatose patient with 500 mg. of chlortetracycline in 500 ml of 5 per cent glucose intravenously and 100 mg of cortisone intramuscularly every 6 hours for 3 doses Twelve hours later the intravenous administration of chlortetracycline was repeated This dosage was repeated twice within the next 24 hours, then once daily for 3 days The patient's clinical picture improved within 6 hours, and the improvement was continuous Within 18 hours after starting chlortetracycline and cortisone therapy, she was able to take fluids by mouth The temperature returned to normal after 24 hours Her convalescence from then on was uneventful Similarly, Workman et al (1952) reported that 9 cases infected with Rocky

casionally, a slight antigenic overlap was found in the ESS tests between Rocky Mountain spotted fever and typhus, but otherwise clear-cut differentiation was observed. These observations certainly merit further study.

Treatment

In the early days, the only treatment for spotted fever was good nursing care and symptomatic treatment Metaphen, sulfanilimide, sulfapyridine, penicillin and streptomycin have been tried with no definite evidence of benefit The sulfonamides are not only useless but actually harmful Numerous reports in the early literature described attempts to produce an immune serum for treatment The most promising work along these lines was that of Topping (1943) who used hyperimmune sera prepared in rabbits by injecting them with living rickettsiae obtained from infected yolk sacs or ticks. The results obtained in a small number of patients indicated that serum treatment reduced the case fatality rate if it was administered before the 3rd day of rash Para-aminobenzoic acid (PABA) has been found useful in the treatment of spotted fever, based on the original work of Snyder et al (1942), who demonstrated in white mice that oral administration of PABA reduced the mortality from experimental murine typhus It has been reported to give favorable results in spotted-fever-infected guinea pigs (Anigstein and Bader, 1945), in chick embryos (Hamilton, 1945), and in human beings (Rose, et al, 1945, Ravenel, 1947) It is now a matter of record, however, that the problem of treatment of spotted fever as well as of all other rickettsial diseases essentially has been solved, for there are now available at least 3 antibiotics—chlortetracycline, chloramphenicol and oxytetracycline—which have been proved to be of great value not only in the laboratory but also by repeated clinical test Each of these antibiotics has been used with remarkable results and each has been found to be far superior to immune serum or para-aminobenzoic acid In addition, tetracycline has been shown to be quite effective in the treatment of epidemic typhus fever, and there is every reason to believe that it would be equally beneficial in the treatment of diseases of the spotted-fever group (Yanez, 1957)

Extensive laboratory studies with chlortetracycline have been reported by Wong and Cox (1948) and Anigstein et al. (1948), on the use of chloramphenicol by Smadel and Jackson (1947) and Smadel et al. (1949); and on the efficacy of oxytetracycline by Snyder et al. (1950), Smadel et al (1950) and Rose (1950). Numerous clinical tests carried out by competent observers have fully substantiated the laboratory results

For therapy with chlortetracycline see Cooke (1948), Havens and Stickney (1950), Ross et al (1948); for results with chloramphenicol, see Pincoffs et al (1948), Parker et al. (1950); for oxytetracycline, see Powell et al. (1951). Good reviews on the subject have been written by Finland et al. (1949), Rose and Kneeland (1949), Smadel (1949, 1951) and Harrell (1952).

All of the above-named antibiotics are rickettsiostatic in their action and not rickettsiocidal. The antibiotics suppress the growth of the rickettsiae while the patient overcomes the disease by developing immunity and consequent control of the infectious agent After recovery, the host may continue to harbor living rickettsiae for considerable periods of time The matter of drug dosage for any of the rickettsioses, including spotted fever, is relatively simple and essentially the same The administration of 2.0 to 3 0 Gm orally, in divided doses, each day until the patient's temperature has been normal for 48 to 72 hours is a good general rule to follow Smadel (1951) has recommended an initial loading dose of 3 0 Gm when chloramphenicol is used It is not necessary to use such a loading dose for chlortetracycline or oxytetracycline In the case of chlortetracycline it is recommended that the daily amount of drug given orally be approximately 100 mg. per 10 pounds body weight; the total amount should be divided and given at 3- to 4-hour intervals The antibiotics are most effective when they are given early in the course of the illness Thus, it is of utmost importance to be aware of the possibility of spotted fever in any area where ticks occur even though no human cases have been reported It is important to keep in mind, too, that antibiotics prevent further damage caused by the action of the organism but do not repair damage that has already occurred Spotted-fever patients usu-

Mountain spotted fever gave a better response with a combined treatment of chloramphenicol and cortisone than would be expected with chloramphenicol alone Cortisone in 25 mg tablets was given orally in 3 cases, and cortisone acetate suspension (25 mg per ml) was given intramuscularly in 6 cases Adults received an initial dose of 200 mg. followed by 2 doses of 100 mg each at 6-hour intervals Children were given approximately two thirds the adult dose In all cases, the total duration of cortisone therapy did not exceed 12 hours Clinical improvement was uniformly observed within 24 hours or less after the initiation of combined therapy. The most striking observations were the prompt relief of headache and toxemia, and the return of appetite No deaths occurred The mean duration of fever after the start of combined [illegible]

[illegible] prevent the often severe residual cerebral and myocardial damage suffered by patients with Rocky Mountain spotted fever Harrell (1952) has also called attention to the necessary supportive measures, such as diet and good nursing care, that must be followed even with adequate antibiotic therapy in order to lessen the residual damages produced by the disease.

EPIDEMIOLOGY

Until 1930, spotted fever was believed to be confined to the northwest mountainous portions of the United States, although a case was reported in Indiana in 1925. At present, the disease has been reported from 46 states, the exceptions being Maine and Vermont (Dauer, 1957). It has also been recognized in Canada (British Columbia, Alberta and Saskatchewan), in Mexico (the northern part of the state of Sinaloa, the southern part of the state of Sonora, and parts of the states of Coahuila and Durango [Silva-Goytia and Elizondo, 1952]), in Brazil (São Paulo, Rio de Janeiro and Minas Gerais), in Panama (De Rodaniche and Rodaniche, 1950, Calero [illegible]

[illegible] *fiebre de Choix, fiebre pinta* and *fiebre manchada;* in Brazil it has been called exanthematic typhus of São Paulo or Minas Gerais typhus, whereas in Colombia it was originally designated Tobiã fever. For incidence of spotted fever in the western hemisphere see Tables 37 and 38.

In the western United States, most cases are reported in April, May and early June, the season of prevalence of the Rocky Mountain wood tick, *Dermacentor andersoni.* In sections of higher altitudes, such as Wyoming and Colorado, the danger period may extend into the summer. Occasional cases have been reported during the late summer, fall and even winter months. In the eastern United States, most cases occur during the summer, the season of the greatest activity of the American dog tick, *Dermacentor variabilis.* In the West, most cases occur in adult males since they, through vocational pursuits, are more exposed to tick-bites Persons living in live-stock range areas and particularly those handling sheep are in greatest danger. Other groups affected are forest service personnel, highway construction workers, railroad-section hands, prospectors, miners, trappers, hunters, fishermen, campers and tourists. Only a relatively small percentage of the cases occurs in city dwellers because of the fact that *D. andersoni* is generally found in the areas removed from habitation and ordinarily does not infest domestic animals On the other hand, in the East a high percentage of infections is among children and women [illegible] that [illegible] only

The virulence of the infection varies with the locality and is correlated in any selected area with the maximum level of virulence of the strain of rickettsia in the local tick population In the Bitter Root Valley of western Montana, the death rate for nonvaccinated

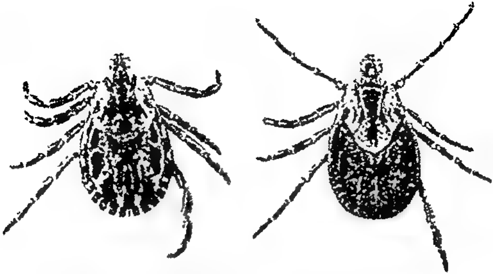

FIG 129 *Dermacentor variabilis* (*Left*) Male (*Right*) Female (Photograph from Dr R A Cooley, U S Public Health Service, Hamilton, Mont)

adults averages about 80 per cent and for children about 37 5 per cent A high case fatality rate also prevails in other parts of western Montana, in certain parts of Wyoming and Oregon, in all affected portions of northern Idaho, and along the extreme eastern edge of Washington In other areas of the West, notably southern Idaho, the case fatality rate varies with a minimum of at least 10 per cent (Parker, 1938) On the average, spotted fever in the East is about as fatal as it is in the West In comparing data for a 10-year period (1930-1939 inclusive), Topping (1941) reported that the crude fatality rate for Idaho and Montana was 28 1 per cent, while for Maryland and Virginia it was 18 4 per cent Little difference was found in the fatality rates when the two areas were compared on the basis of age In the western states, one half of the cases (50 2%) occurred in persons aged 40 years or over, while in the eastern states this was practically reversed with the largest number (46 8%) occurring in persons under 15 years of age As

already indicated, in the East, the incidence among females (39.4%) was considerably higher than in the West (16.5%). For additional information concerning the epidemiology of spotted fever in Maryland and Virginia, see Price (1954) and Cawley and Wheeler (1957), respectively.

The following brief outline of the distribution of known vectors and of those shown experimentally to be capable of transmitting spotted fever will serve to indicate the wide dispersal of ticks and the threat they represent to man (Steinhaus, 1946; Philip, 1942; Parker et al., 1933; Spencer and Parker, 1923, Davis, 1942, 1943a, b; Davis et al., 1941, Patiño-Camargo, 1941; Parker, 1938; Parker et al, 1943, Kohls, 1948) Within the United States, 4 species of ticks have been recognized as natural carriers: the Rocky Mountain wood tick, *D andersoni;* the Amer-

In Canada, the natural vector of spotted fever is *D andersoni*. In Mexico, naturally infected specimens of the common dog tick, *Rhipicephalus sanguineus*, have been reported found in the states of Sinaloa, Sonora, the lake region (Comarca Lagunera) of the states of Coahuila and Durango and in the states of San Luis Potosi (city of San Luis Potosi), Nuevo Léon (Montemorelos) and Michoacan (Morelia). Also, specimens of naturally infected *A. cajennense* have been reported in the city of Vera Cruz In addition to the above, Silva-Goytia and Elizondo (1952), in studies carried out in the Comarca Lagunera area, reported the isolation of spotted fever strains from *Ornithodorus nicollei* collected inside a room and on dogs, larvae of *Otobius lagophilus* collected on burros; and *R. sanguineus* collected on dogs and horses. These authors also reported the possible isolation of a spotted-fever strain of rickettsiae from human lice. They could not maintain the strain in guinea pig passage but claimed that it gave immunity to their experimental animals In both Colombia and Brazil, the principal natural vector is believed to be *A. cajennense*.

Ticks that may be placed in the category of potential carriers or that have been shown experimentally to be capable of transmission are· in the United States—the Cayenne tick, *Amblyomma cajennense;* the Pacific Coast tick, *D occidentalis;* the rabbit dermacentor, *D parumapertus;* the brown dog tick, *R. sanguineus; Ornithodorus parkeri; D. albipictus; O. hermsi; O. nicollei; O. turicata* and *O. rudis;* in Brazil—*A. striatum, A. brasiliense, R. sanguineus* and *O. rostratus;* in Colombia—*Anocentor nitens, O. rudis* and *R. sanguineus.*

Of all the ticks, *D. andersoni* has been studied most extensively in relation to spotted fever. It is found throughout the Rocky Mountain region and adjacent areas Rickettsiae may be found in all stages of the tick, from the egg through the adult; they may be transmitted during copulation, and infected females pass them to their progeny. So far as is known, the only way in which the rickettsiae survive the winter is in infected nymphs and adult ticks. Developmental forms of ticks feed on a great variety of small wild animals, principally rodents and rabbits, many of which are susceptible to spotted fever. Adult ticks mainly infect large wild and domestic animals but are also found on jack rabbits and porcupines The larvae are active during the summer, and the nymphs and the adults during spring and early summer. At higher altitudes, their activity may occur at later periods of the year The life cycle is normally completed in 2 years Adult ticks bite man readily, and occasionally nymphs have been found attached to children

D. variabilis is closely related, both morphologically and biologically, to *D. andersoni* (Cooley, 1938; Smith et al, 1946). It is found in the Great Plains region extending eastward to the Atlantic Coast and occurs sporadically in California and south-central Oregon To the south, it reaches into Mexico. In Canada, it occurs eastward from southern Manitoba and has even been reported in Labrador. Developmental forms feed on rodents, but certain species of mice are apparently more favored The dog is by far the preferred host of the adults, although they also feed on deer, cattle and other large, domestic or wild animals Nymphs engorge over a period of months and have been found feeding even during the winter Adult ticks appear in late spring and remain active longer during the summer than does *D andersoni* The importance of this tick lies in its close relationship with dogs and human habitations, the adult tick bites man readily.

Amblyomma americanum has been studied less intensively than either *D andersoni* or *D variabilis.* It is prevalent in the southern states around the Gulf Coast, occurs in southeastern and south-central parts of the United States and has been reported in Labrador and in South America as far down as Argentina. It feed

domestic animals and on certain species of birds. The immature stages, unlike those of *D. andersoni* and *D variabilis*, are commonly found on the same host animals as the adult ticks All stages of this tick attack man, and the larvae and the nymphs are notorious pests (Cooley and Kohls, 1944, Kohls, 1948)

Haemaphysalis leporis-palustris occurs throughout the United States, extending northward to central Alaska and the southern end of Hudson Bay and southward into South America This tick, in all stages, is largely restricted to the several species of wild rabbits and to certain ground-frequenting birds Several thousand ticks are sometimes found on a single host The importance of this tick to spotted fever does not depend on its direct connection with man, whom it rarely attacks, but upon the fact that by feeding on rabbits it supplies a possible source of rickettsiae for the *D andersoni*, *D variabilis* and *A americanum* feeding simultaneously on the the same host rabbit Thus, the rabbit tick, which spontaneously transmits spotted fever to rabbits, must be considered as a potent factor in the prevalence of spotted fever rickettsiae in the man-infesting species of ticks in the United States and Canada *H leporis-palustris* is prevalent in the northern United States from early spring to early fall, but in the South its period of activity is considerably extended Under favorable conditions, its life cycle is completed in 1 year *H leporis-palustris* consistently carries strains of spotted fever much milder or less virulent than those usually isolated from *D andersoni* (Parker, et al, 1951)

Rhipicephalus sanguineus is quite widespread but is especially prevalent in the warmer climates It is abundant in the Gulf Coast states and has been reported in Massachusetts, Ohio, Minnesota and even Nova Scotia It has been reported found naturally infected in the United States (Anigstein and Bader, 1943, and in Mexico (Bustamente et al, 1946) This species commonly attacks man in Europe and Africa, but in the United States there are few records of any forms hav-

animals as well as certain wild and domestic fowl It has been shown to be a vector of spotted fever in Brazil, Colombia and Mexico It is fortunate that its distribution within the United States is limited, since it is a vicious parasite of man in all its stages

Dermacentor occidentalis is found in California west of the Cascade Mountains and extends northward to central Oregon This tick, although limited in distribution, is nevertheless important because it could convey spotted fever to man and, in addition, will hybridize with *D. andersoni* (Cooley, 1938) The immature stages usually feed on rodents and other small animals, but they have also been found on cattle (Herms and Howell, 1936) The adults are found on larger animals such as deer, cattle and horses

Dermacentor parumapertus is found mainly in the southwestern areas of the United States which thus far are of minor importance in the epidemiology of spotted fever However, strains of rickettsiae related to the spotted fever group have recently been isolated from lots of the "rabbit dermacentor" tick collected in northern Nevada (Philip and Hughes, 1953, Philip et al, 1955) In the northern regions, its distribution overlaps that of *D andersoni* and in the West and the Northwest both that of *D. occidentalis* and *D variabilis* *D parumapertus* has been found, thus far, almost exclusively on rabbits, but occasionally it has been collected

taneously feeding

The winter tick, *Dermacentor albipictus*, has been strongly incriminated by circumstances in which a human case of Rocky Mountain spotted fever followed a tick-bite (Philip and Kohls, 1951) This is an interesting observation, since *D albipictus* rarely has been observed to attach itself to man even in areas where it is abundant on animals

Ornithodoros parkeri is found in the burrows and the nests of rodents in the northwestern states It has been shown to be an

fever rickettsiae in unfed adult ticks However, inoculation was apparently the most reliable method for testing ticks that had been fed recently No demonstrable infection resulted when infected, unfed ticks were inoculated into guinea pigs, but many of the

already indicated, in the East, the incidence among females (39 4%) was considerably higher than in the West (16 5%). For additional information concerning the epidemiology of spotted fever in Maryland and Virginia, see Price (1954) and Cawley and Wheeler (1957), respectively.

The following brief outline of the distribution of known vectors and of those shown experimentally to be capable of transmitting spotted fever will serve to indicate the wide dispersal of ticks and the threat they represent to man (Steinhaus, 1946, Philip, 1942, Parker et al., 1933, Spencer and Parker, 1923, Davis, 1942, 1943a, b, Davis et al., 1941; Patiño-Camargo, 1941; Parker, 1938, Parker et al, 1943; Kohls, 1948). Within the United States, 4 species of ticks have been recognized as natural carriers· the Rocky Mountain wood tick, *D andersoni*, the American dog tick, *D. variabilis*, the lone star tick, *Amblyomma americanum*, and the rabbit tick, *Haemaphysalis leporis-palustris*.

In Canada, the natural vector of spotted fever is *D andersoni* In Mexico, naturally infected specimens of the common dog tick, *Rhipicephalus sanguineus*, have been reported found in the states of Sinaloa, Sonora, the lake region (Comarca Lagunera) of the states of Coahuila and Durango and in the states of San Luis Potosi (city of San Luis Potosi), Nuevo Léon (Montemorelos) and Michoacan (Morelia). Also, specimens of naturally infected *A cajennense* have been reported in the city of Vera Cruz In addition to the above, Silva-Goytia and Elizondo (1952), in studies carried out in the Comarca Lagunera area, report

from

room

lus collected on burros; and *R. sanguineus* collected on dogs and horses. These authors also reported the possible isolation of a spotted-fever strain of rickettsiae from human lice They could not maintain the strain in guinea pig passage but claimed that it gave immunity to their experimental animals In both Colombia and Brazil, the principal natural vector is believed to be *A cajennense*

Ticks that may be placed in the category of potential carriers or that have been shown experimentally to be capable of transmission are: in the United States—the Cayenne tick, *Amblyomma cajennense;* the Pacific Coast tick, *D. occidentalis;* the rabbit dermacentor, *D. parumapertus;* the brown dog tick, *R. sanguineus; Ornithodorus parkeri; D. albipictus; O. hermsi; O. nicollei; O. turicata* and *O. rudis;* in Brazil—*A. striatum, A. brasiliense, R. sanguineus* and *O rostratus;* in Colombia—*Anocenter nitens, O. rudis* and *R. sanguineus.*

Of all the ticks, *D. andersoni* has been studied most extensively in relation to spotted fever. It is found throughout the Rocky Mountain region and adjacent areas. Rickettsiae may be found in all stages of the tick, from the egg through the adult; they may be transmitted during copulation, and infected females pass them to their progeny. So far as is known, the only way in which the rickettsiae survive the winter is in infected nymphs and adult ticks. Developmental forms of ticks feed on a great variety of small wild animals, principally rodents and rabbits, many of which are susceptible to spotted fever. Adult ticks mainly infect large wild and domestic animals but are also found on jack rabbits and porcupines The larvae are active during the summer, and the nymphs and the adults during spring and early summer. At higher altitudes, their activity may occur at later periods of the year. The life cycle is normally completed in 2 years Adult ticks bite man readily, and occasionally nymphs have been found attached to children

found in the Great Plains region extending eastward to the Atlantic Coast and occurs sporadically in California and south-central Oregon. To the south, it reaches into Mexico. In Canada, it occurs eastward from southern Manitoba and has even been reported in Labrador Developmental forms feed on rodents, but certain species of mice are apparently more favored. The dog is by far the preferred host of the adults, although they also feed on deer, cattle and other large, domestic or wild animals. Nymphs engorge over a period of months and have been found feeding even during the winter. Adult ticks appear in late spring and remain active longer during the summer than does *D. andersoni* The importance of this tick lies in its close relationship with dogs and human habitations; the adult tick bites man readily.

Amblyomma americanum has been studied less intensively than either *D. andersoni* or *D variabilis*. It is prevalent in the southern states around the Gulf Coast, occurs in southeastern and south-central parts of the United States and has been reported in Labrador and in South America as far down as Argentina. It feeds on a variety of wild and

domestic animals and on certain species of birds The immature stages, unlike those of *D andersoni* and *D. variabilis*, are commonly found on the same host animals as the adult ticks All stages of this tick attack man, and the larvae and the nymphs are notorious pests (Cooley and Kohls, 1944, Kohls, 1948)

Haemaphysalis leporis-palustris occurs throughout the United States, extending northward to central Alaska and the southern end of Hudson Bay and southward into South America. This tick, in all stages, is largely restricted to the several species of wild rabbits and to certain ground-frequenting birds Several thousand ticks are sometimes found on a single host The importance of this tick to spotted fever does not depend on its direct connection with man, whom it rarely attacks, but upon the fact that by feeding on rabbits it supplies a possible source of rickettsiae for the *D andersoni*, *D variabilis* and *A americanum* feeding simultaneously on the the same host rabbit Thus, the rabbit tick, which spontaneously transmits spotted fever to rabbits, must be considered as a potent factor in the prevalence of spotted fever rickettsiae in the man-infesting species of ticks in the United States and Canada *H leporis-palustris* is prevalent in the northern United States from early spring to early fall, but in the South its period of activity is considerably extended Under favorable conditions, its life cycle is completed in 1 year *H. leporis-palustris* consistently carries strains of spotted fever much milder or less virulent than those usually isolated from *D andersoni* (Parker, et al , 1951)

Rhipicephalus sanguineus is quite widespread but is especially prevalent in the warmer climates It is abundant in the Gulf Coast states and has been reported in Massachusetts, Ohio, Minnesota and even Nova Scotia. It has been reported found naturally infected in the United States (Anigstein and Bader, 1943, and in Mexico (Bustamente et al., 1946) This species commonly attacks man in Europe and Africa, but in the United States there are few records of any forms having been found on hosts other than the dog, which is the principal host of all stages

Amblyomma cajennense is found in southern Texas and Florida and is abundant in Mexico, Central America and parts of South America It parasitizes a variety of wild and domestic animals as well as certain wild and domestic fowl It has been shown to be a vector of spotted fever in Brazil, Colombia and Mexico It is fortunate that its distribution within the United States is limited, since it is a vicious parasite of man in all its stages

Dermacentor occidentalis is found in California west of the Cascade Mountains and extends northward to central Oregon This tick, although limited in distribution, is nevertheless important because it could convey spotted fever to man and, in addition, will hybridize with *D. andersoni* (Cooley, 1938) The immature stages usually feed on rodents and other small animals, but they have also been found on cattle (Herms and Howell, 1936) The adults are found on larger animals such as deer, cattle and horses

Dermacentor parumapertus is found mainly in the southwestern areas of the United States which thus far are of minor importance in the epidemiology of spotted fever However, strains of rickettsiae related to the spotted fever group have recently been isolated from lots of the "rabbit dermacentor" tick collected in northern Nevada (Philip and Hughes, 1953, Philip et al , 1955) In the northern regions, its distribution overlaps that of *D andersoni* and in the West and the Northwest both that of *D occidentalis* and *D variabilis* *D parumapertus* has been found, thus far, almost exclusively on rabbits but occasionally it has been collected on deer, coyote and man Its chief importance would be its conveyance of spotted fever to rabbits on which developmental forms of other known vectors of the disease were simultaneously feeding

The winter tick, *Dermacentor albipictus*, has been strongly incriminated by circumstances in which a human case of Rocky Mountain spotted fever followed a tick-bite (Philip and Kohls, 1951) This is an interesting observation, since *D albipictus* rarely has been observed to attach itself to man even in areas where it is abundant on animals

Ornithodoros parkeri is found in the burrows and the nests of rodents in the northwestern states It has been shown to be an efficient vector of spotted fever (Davis, 1942) It rarely bites man spontaneously, but it will do so readily in the laboratory

Spencer and Parker (1923) reported that it was unwise to rely upon feeding or inoculation alone as an index of the presence of spotted fever rickettsiae in unfed adult ticks However, inoculation was apparently the most reliable method for testing ticks that had been fed recently No demonstrable infection resulted when infected, unfed ticks were inoculated into guinea pigs, but many of the

animals were found subsequently to be immune to spotted fever. The transition of the rickettsiae from a nonvirulent, immunizing phase to a virulent, infection-producing phase, brought about by the ingestion of fresh blood was called "reactivation." As Spencer and Parker (1923) pointed out, "It is not known whether this transition is due to multiplication of the virus, to development of a possible distinct stage in its life cycle, to renewal of virulence following a period of attenuation, or perhaps some other unrecognized condition initiated by the ingestion of fresh mammalian blood." The "reactivation" phenomenon probably explains why ticks do not infect unless they have been attached and have fed for several hours. Ricketts, 1907a, observed an immunizing phase of rickettsiae in tick eggs Spotted-fever infection was produced by the injection of from 5 to 80 eggs recently laid by an infected female tick However, immunity instead of frank infection was produced with eggs that had been dried for 4 months Spencer and Parker (1923) likewise produced immunity in guinea pigs by injecting them with comparatively fresh eggs from an infected rabbit tick, *H leporis-palustris*.

Spencer and Parker (1930) showed that tick rickettsiae would produce infection of guinea pigs through the unabraded skin and uninjured conjunctival sacs, and they suggested that infection of man in this way is a distinct possibility and doubtless occurs occasionally Infection in such a manner could occur if an infected tick were crushed between the fingers when handpicking ticks from domestic animals or when handling tick-infested small animals (rabbits, ground squirrels, etc.) that had been trapped or shot. Fresh tick feces are also infectious, but the rickettsiae in feces are much less virulent than those in tick tissue and apparently do not infect through unabraded skin However, both tick tissues and feces can produce infection through an abrasion. Dried tick feces rapidly lose their infectiousness, so that infection via the respiratory tract by dry, airborne feces, as happens with louse feces in epidemic typhus, is not likely.

Control Measures

There are 3 possible ways of preventing spotted-fever infection (1) personal care, (2) vaccination and (3) use of tick-control methods.

Under personal care are included avoidance of tick-infested areas, use of tick repellents, the wearing of suitable clothing so as to minimize the possibility of tick-bites, and the early removal of ticks that may become attached to the body. Known infested areas should be avoided as much as possible during the tick season; however, it is recognized that this is not possible for many persons living in affected areas. Furthermore, any area in which a tick vector is present is potentially dangerous, and the areas in which the disease is known to exist are constantly expanding Certain precautions should be taken by persons entering tick-infested areas. Camp sites should not be located where small animals are numerous, since ticks would be found more frequently in such areas A tick-repellent, such as N-butylacetanilide solution should be distributed uniformly throughout the outer garments It is important to wear proper clothing (the shirt should be tucked inside the trousers, and high boots, leggings or socks should be worn outside the trouser legs) so that ticks will find it more difficult to become attached

If one spends much time in tick-infested country, some ticks will reach the body in spite of all precautions. However, since ticks seldom attach themselves to the skin immediately, and rarely transmit infection until they have fed for several hours, an effective method of prevention is to remove the clothing and search both the clothing and the body for ticks at least twice each day Attached ticks should be removed immediately by grasping the body of the tick with small forceps, gloved fingers or with a piece of paper held between the fingers, and pulling gently. Bare fingers should not be used because of the danger of contamination with rickettsiae Twisting the tick or pulling it forcibly may cause it to break and leave the mouthparts in the skin. The wound itself should be treated with an antiseptic solution, such as tincture of iodine There is nothing characteristic which will distinguish the bite of an infected tick from that of a noninfected one

Vaccination is an effective method of prophylaxis Two types of vaccine are available A preparation made from the tissues of infected ticks (*D. andersoni*) is prepared and distributed by the Rocky Mountain Laboratory, United States Public Health Service,

Hamilton, Mont. A second type of vaccine, prepared from rickettsiae grown in the yolk-sac tissue of fertile hen's eggs (Cox, 1941; 1948), is produced by certain commercial manufacturers of biologics in the United States.

All evidence from animal experiments, as well as from use in human beings, indicates that the yolk-sac and the tick vaccines stimulate the same degree of immunity It is recommended that these vaccines be given either subcutaneously or intramuscularly in 3 injections of 1 0 ml each, or in 2 injections of 2 0 ml each, at 5- to 7-day intervals They should be administered in the winter or early spring, before the advent of the tick season, and should be repeated each year, since the maximum degree of protection is retained for less than a year. Those individuals sensitive to chick or egg proteins should be given the tick-tissue vaccine

The vaccines have definite protective value The degree and the duration of immunity vary with the individual vaccinated and with the virulence of regional strains of spotted fever The vaccine usually affords complete protection against relatively mild strains but may be less effective against more virulent ones Most children are fully protected against even the highly fatal types of spotted fever, whereas adults are fully protected only occasionally However, in the latter, the degree of protection is sufficient to modify the severity of the disease and to ensure recovery in practically all cases It is questionable that the vaccine is of value after infection has been acquired, it is of no value in treatment after onset of illness In 1941, Cox reported on the development of a living, avirulent strain of spotted fever rickettsiae derived from *D variabilis* by continued passage in the yolk sac of fertile hens' eggs and suggested that it might be of value for immunization of human beings, but no practical follow up has been made thus far.

With the advent of the antibiotics, some persons believe that there is now no need for vaccination However, persons who are exposed to more than ordinary risk should be vaccinated It is well known that spotted fever has proved to be fatal in unvaccinated persons who have been treated with antibiotics late in the course of the disease Thus, preventive as well as therapeutic measures should be practiced where the incidence of spotted fever is high.

During the past few years, it has been shown that roadside and pathside control of *D. variabilis* and *A americanum* is so readily obtained with insecticides that chemical control is of practical value in inhabited areas where spotted fever is a serious hazard or even where tick annoyance only is a problem Smith et al (1946) pointed out that the adults of the American dog tick (*D. variabilis*) tend to concentrate on the grass at the sides of the roads and paths They reported that a spray containing 0 5 per cent DDT (2,2 bis [p-chlorophenol]-1,1,1-trichlorethane), 2.5 per cent of soluble pine oil and 97 per cent water, applied to roadside vegetation at the rate of 7 pounds of DDT per acre, was not injurious to foliage and reduced tick abundance to less than 1 per cent of the original infestation for 10 days, whereas tick abundance in an untreated area, ranged from 82 to 106 per cent during the same time. Glasgow and Collins (1948) reported that DDT applied at the rate of 1 pound per acre, in the form of dusts, solutions, emulsions or suspensions, gave excellent control at a lower cost for materials than any other acaricide tested Benzene hexachloride used at the rate of 1 pound of the gamma isomer per acre apparently gave equally good results but cost more

Therrien et al (1954) found dieldrin applied as a dust at 1 pound per acre was more effective in controlling *A americanum* than any of the other chemicals tested McCroan et al (1955) likewise reported good results in the control of ticks by chemical methods They used widestrip spraying equipment in which mist generators gave excellent coverage of a 50- to 100-foot strip along roadways They state that "if rosin-DDT emulsion is used in a good mist machine, 1 5 pounds of DDT per acre gives good residual control of *D variabilis* for an entire tick season" The rosin-DDT emulsion did not burn the vegetation when applied along roadsides

TICK-BORNE TYPHUS

(Synonyms boutonneuse fever, *fièvre boutonneuse*, Kenya typhus, South African tick bite fever, *fièvre escharonodulaire*, ex-

animals were found subsequently to be immune to spotted fever. Pathologic Picture

In man the microscopic pathologic lesions are characteristic of the rickettsial diseases and consist of thrombosis of the capillaries and the small arteries and veins, resulting from lesions of the vascular endothelium. The thrombosis is associated with the development of perivascular nodules In guinea pigs, the pathology duplicates in all essential details that of spotted fever (Hass and Pinkerton, 1936). Intraperitoneal inoculation of adult male guinea pigs with infected blood from a patient causes a high fever, following an incubation period of 4 to 7 days The reac-

sacrificed at the height of fever (2nd or 3rd day) show the spleen to be 2 or 3 times larger than normal, the testes are injected, and the tunicae may be adherent to the scrotal sac Frequently, the testicles and the spleen are covered with a whitish exudate In the infected cells, rickettsiae may be seen both intra- and extranuclear Inoculated rats and gerbils show only inapparent infections

Experimental Infection, Host Range

Durand (1932a) produced the disease experimentally in 13 human beings in 3 by inoculation of triturated infected ticks, in 7 by inoculation of blood from naturally infected patients, in 2 by inoculation of brain suspensions from animals inoculated with blood from naturally infected patients, and in 1 by inoculation of a *tâche noire* taken at biopsy Blanc and Caminopétros (1932) demonstrated that the disease could be reproduced experimentally in human beings by subcutaneous inoculation or by application of macerated infected tick tissue to slightly traumatized conjunctivae In North Africa, and more generally in the Mediterranean basin, dogs undoubtedly play an important role and they, particularly pups, probably constitute the chief animal reservoir Blanc and Caminopétros (1932) were unsuccessful in their attempts to infect dogs either with the blood of patients in the stage of full eruption or with proved infected ticks, but Durand (1932b) succeeded in showing their susceptibility Blanc and Caminopétros (1932) have shown that white mice may have inapparent infections, and that the Macedonian spermophile (*Citellus citellus*) is highly susceptible but because of its limited habitat could not be considered as a universal reservoir of the rickettsiae Durand and Laigret (1932) extended the studies to wild rodents of France and Africa which, because of their association with human habitations, could be considered as potential hosts of the vector *Mus barbarus*, *Jaculus jaculus* and *Meriones shawi*, found frequently around Tunis, were fully resistant to infection. Inapparent infections were obtained with 2 white rats (*Mus rattus*), while from the gerbil (*Gerbillus campestris*) they succeeded in passing the infection to man by inoculating a mixture of blood and brain tissue from an infected animal. Blanc and Caminopétros (1932) suggested that a vertebrate host is not essential for maintenance of the rickettsiae, and that ticks can maintain the cycle not only because they remain infectious after hibernation but also because they transmit the infection through their eggs In South Africa, it appears that tick-borne typhus is not necessarily related to dogs, for infection is transmitted by ticks which are veld dwellers and not found on domestic animals, Gear, 1938 However, Alexander and Mason (1939) reported the isolation of a strain from a tick-infested dog that became ill More recently, Gear (1954) reported the isolation of a strain of rickettsiae

also showed a positive complement-fixation test for tick-borne typhus and, judging by the results of complement-fixation tests, it would appear that a considerable number of rats in the suburban areas of Johannesburg are infected However, it was believed that rats, like man, were infected by ticks picked up

irroratus) showed positive reactions with *R conorii*, thus indicating past infection with this rickettsia This lead was followed up, and a strain of tick-borne typhus was isolated from the brain of the vlei rat For a good chart depicting the present concept of the natural history of *R conorii*, as it occurs in South Africa at least, see Gear (1954)

anthème typhoïde estival, dothiendermie aigue, exanthème infectieux épidémique, exanthematous fever, eruptive fever, Marseilles fever, fever of Conor and Bruch)

Introduction

Tick-borne typhus is a tick-borne, typhus-like, febrile disease, generally mild in nature, often characterized by a black spot, *tâche noire*, at the site of tick-bite, swelling of the corresponding lymph nodes, and a maculopapular eruption that covers the entire body, including the palms of the hands and the soles of the feet.

History

Conor and Bruch first described the disease as a clinical entity in Tunis, North Africa in 1910. In 1911, Nuttall gave the name "tick-bite fever" to a similar disease described independently by McNaught, 1911, and Sant' Anna, 1911. Comparative studies carried out by Pijper, 1936, and Pijper and Dau, 1934, on spotted fever, boutonneuse fever and tick-bite fever led them to the conclusion, Pijper, 1936, that "tick-bite fever must be regarded as a rickettsiosis *sui generis* and that it deserves a place by itself in the group" However, the studies of Mason and Alexander, 1939a, b; Gear and Bevan, 1936, Gear and Douthwaite, 1938, Gear, 1938, Gear and De Meillon, 1939, and Gear (1950) showed that there was complete cross immunity between tick-bite fever of South Africa and boutonneuse fever of North Africa

All present evidence indicates that the boutonneuse fever infections that have been reported from practically all of the Mediterranean countries of Europe, Asia and Africa (cf. Olmer and Olmer, 1956) and the other tick-borne rickettsioses found throughout Africa, such as Kenya typhus, Nigerian typhus, tick typhus of Abyssinia and South African tick-bite fever, should be grouped together under the general terminology of tick-borne typhus, of which *R conorii* is the causative agent (Joint OIHP/WHO Study Group on African Rickettsioses, 1950)

Clinical Picture

The incubation period generally is from 5 to 7 days, although occasionally it may be [illegible] from 8 to 14 days with defervescence taking place by rapid lysis Associated symptoms are a violent and persistent headache, commonly frontal, but which may be retro-orbital or general; a feeling of lassitude, and pains in various joints and muscles Photophobia is often present. Bulbar conjunctivae may be hyperemic and slightly edematous. The eyeballs may be sore. There may be mental confusion and delirium The tongue is usually coated, peeling at the sides and the tip. Frequently (in about 80% of cases) at the time of onset a small ulcer (black spot, *tâche noire*) from about 2 to 5 mm in diameter, showing a black necrotic center surrounded by a dark reddish area of variable dimensions, appears at the site of the tick-bite and may persist until the temperature falls. The *tâches noires* may be found on any part of the body, usually on those covered by clothing, and invariably are accompanied by enlargement and tenderness of the regional lymph nodes. Usually 3 or 4 days after the initial chill, a maculopapular eruption develops. The rash is usually first noticed on the forearms as discrete rose-colored elevated spots The rash spreads rapidly over the whole body involving the palms, the soles and even the face. It increases in density over the next few days. The rash, in severe cases, may become hemorrhagic, especially on the lower limbs The rash on the abdomen may be less pronounced than elsewhere Small, round, red spots which persist only a few days may be found on the soft palate The macules, which at first disappear on pressure, are small, clearly outlined and separated by healthy skin They soon become papular, are occasionally hemorrhagic and may persist for some time after defervescence. The eruption disappears without leaving residual traces and there is no desquamation During the febrile stage the patient often shows mental excitement giving way to a very marked depression during convalescence. Marked weakness is characteristic of convalescence with a tendency to tachycardia on exertion The prognosis is usually good However, the disease is not always mild, since both Gear, 1938, and Dezest (1953) have described grave forms with complications or death in aged or physically deficient persons For a good clinical picture of tick-borne typhus in Kenya, East Africa, see Harris (1952).

most certainly tick-borne typhus The reaction with Proteus OXK apparently is even more frequent, and the titers on the average are higher than with OX2 or OX19 (Joint OIHP/WHO Study Group on African Rickettsioses, 1950) The agglutination titers with Proteus organisms are generally low, varying between 1 50 and 1 500 The lowest reliable, suggestive titer is 1 50 However, with the use of the Weil-Felix test alone, it is not possible to differentiate tick-borne typhus from epidemic (louse) or murine (flea-borne) typhus The need for a more specific test has been met by the use of specific rickettsial agglutination and complement-fixation tests. These tests, together with the isolation of the rickettsiae by cultural methods, accurately distinguish tick-borne typhus from either epidemic or murine typhus With washed, purified rickettsial antigens prepared from infected yolk sacs, Plotz et al (1944) showed that tick-borne typhus could be readily differentiated from spotted fever by the complement-fixation reaction However, it must be remembered that a disadvantage of these more specific rickettsial tests is that antibodies may be detectable for many years after the patient's illness, and thus they do not differentiate recent from long previous infection However, the change from a negative to a positive result is of diagnostic value

Treatment

Chlortetracycline has been reported to be a specific treatment for tick-borne typhus (Gear and Harington, 1949, Hildick-Smith, 1949, Yeo, 1950, Harris, 1952, 1953) Following chlortetracycline therapy, normal temperatures were attained in 48 to 72 hours and there were no relapses Chlortetracycline given at the time of the appearance of the primary lesions will abort the febrile attack Choramphenicol likewise has been found to be efficacious, and undoubtedly oxytetracycline would give satisfactory results The treatment schedule for spotted fever is recommended

Epidemiology

Following the description of cases in Tunis in 1910, the disease was reported in France (the Avignon region), Tripoli, Italy, Greece, Crete and Rumania (Blanc and Caminopétros, 1932) Olmer and Olmer (1956) have reviewed rather comprehensively the epidemi-

1933 were the departments of Bouches-du-Rhône, Var, Alpes-Maritimes, Vaucluse, Gard and Herault. Three more recent important foci are Lyon, Toulouse and the department of Landes The disease is found throughout Italy and is not rare in Sicily It has been reported in Spain, Greece, Crete, Turkey,

most common vector is the dog tick *Rhipicephalus sanguineus* Apparently, the disease has not been reported thus far from Jugoslavia and Albania (Olmer and Olmer, 1956) The disease is also widespread throughout all other parts of Africa such as Somaliland, Kenya, Uganda, Nigeria, the Sudan, Tanganyika, Nyasaland, Ghana (the Gold Coast), Sierra Leone, French Guinea, Senegal, Togoland, the Cameroons, Oubangui-Chari, the Belgian Congo, Ruanda-Urundi, the Portuguese colonies of Angola and Mozambique, and all parts of the Union of South Africa In Kenya,

cidence with most cases occurring in the summer months when ticks are numerous In the lowveld where the temperature is more uni-

not been isolated from this species Gear (1954) states, "It seems probable that most species of ixodid ticks are capable of transmitting the disease" It has been demonstrated that all stages of the common dog tick *Haemaphysalis leachi*—larva, nymph and adult—are infective and that there is hereditary transmission of the rickettsiae through

While the monkey is susceptible, the guinea pig is probably the most useful animal for experimental purposes. Tick-borne typhus may be transmitted to them by intraperitoneal injection of patient's blood. Blood taken during the first 5 days of illness or from patients who shortly develop a rash is best for making isolations. Guinea pigs inoculated intraperitoneally show an incubation period of 3 to 6 days, followed by a rise in temperature to 104° to 105° F. for 4 to 6 days, after which the temperature gradually returns to normal. Marked scrotal swelling with the tunicae adherent to the scrotal sac develops, but generally no sloughing results. Transfer of the infection is accomplished most readily by injecting guinea pigs intraperitoneally with testicular and tunica washings or with brain tissue taken from an animal at the height of fever; the minimum infective dose is about 0.003 Gm. Jadin (1951) reported infecting mice by inoculating them intranasally with specimens of ticks (*Haemaphysalis leachi*) taken from a Pekinese dog in Kabgaye, Belgian Congo. The lungs of the mice were filled with rickettsiae, but all attempts to maintain the strain by serial passage in mice failed.

Etiology

The etiologic agent is *R. conorii* (Joint OIHP/WHO Study on African Rickettsioses, 1950)—*Dermacentroxenus rickettsi*, var. *pijperi*, Mason and Alexander, 1939b, named after A. Conor, who, together with A. Bruch, published in 1910 the first clinical description of tick-borne typhus fever (boutonneuse fever) cases occurring in Tunis, North Africa. *R. conorii* is morphologically and tinctorially similar to *R. rickettsii*. As stated previously, all present evidence indicates that *R. conorii* is the etiologic agent of all the tick-borne rickettsial fevers of the Mediterranean countries of Europe, Asia and Africa as well as those found throughout Africa. Ticks, in which the etiologic agent *R. conorii* is hereditary, form the essential reservoir of infection. The rickettsiae live for more than 18 months in infected ticks without producing apparent deleterious effects in their hosts (Brumpt, 1932). Hass and Pinkerton (1936) found rickettsiae in nearly all tissues of infected ticks, particularly in the cells of the gut, the hypoderm and the ovaries where they apparently occur more abundantly shortly after feeding. A few rickettsiae may be found in the testicular exudate of infected guinea pigs, and occasionally in smears from the spleen, but are not found in smears made from the liver, adrenals, lungs, meninges or kidneys. Infected cells may show both intracytoplasmic and intranuclear rickettsiae, although rickettsiae are more often found in the cytoplasm. Like other rickettsiae, they stain well by the Giemsa, Castaneda or Macchiavello methods. The rickettsiae have not been cultivated on artificial media, but they grow readily in plasma-clot, agar-slant or Maitland-type tissue cultures and also in the yolk sac of the developing chick embryo (Cox, 1938). Alexander and Mason (1939) reported that *R. conorii* multiply intranuclearly when grown on the chorio-allantoic membrane of the fertile hen's egg. Intranuclear rickettsiae also are readily found in plasma-clot and agar-slant tissue cultures. Blanc and Caminopétros (1932) reported that *R. conorii* pass L_2 Chamberland candles and claimed that the virulence of human blood is lost after 12 days in an icebox. All attempts to pass *R. conorii* through Berkefeld candles or Seitz filter pads have failed. Guinea pigs recovered from Rocky Mountain spotted fever are solidly immune to tick-borne typhus, and vice versa. However, killed spotted-fever vaccines made from infected *D. andersoni*, which afford complete protection against Rocky Mountain spotted fever in guinea pigs, give no protection against tick-borne typhus (Davis and Parker, 1934; Hass and Pinkerton, 1936).

Diagnosis

In tick-borne typhus, positive serologic reactions appear late in the course of the disease, are rarely obtained before the 10th day of illness, and the maximum titer is usually attained 2 to 4 weeks after defervescence. Gear (1954) states that the average of a large series of cases indicates that Proteus OX19 and Proteus OX2 are agglutinated to

agglutinins may be present in higher titer. A higher agglutination with OX2 than with OX19 indicates the probability of tick-borne typhus; agglutination with OX2 only is al-

been reported to have caused 4 deaths in 12 cases (Le Gac et al., 1952; Le Gac, 1953). An interesting observation is that in the United States the primary lesion (eschar) always heals without leaving a scar, whereas in Africa the primary lesion is much more marked, is followed by considerable necrosis and destruction and always leaves a permanent scar.

Pathologic Picture

The gross appearance of the primary lesion of rickettsialpox is quite similar to the initial lesions seen in scrub typhus and tick-borne typhus. According to Dolgopol (1948), the *microscopic* picture of the primary lesion of rickettsialpox closely resembles the histologic findings of the initial lesions of scrub typhus as described by Allen and Spitz (1945). "The pustules in these two diseases are identical. The difference in the inflammation of the corium is largely quantitative. The area of polymorphonuclear infiltration of the corium in rickettsialpox is more limited and more superficial than in scrub typhus, and there is no degeneration of the connective tissue. The vascular changes also are less severe. The cellular infiltrates follow the same perivascular and periadnexal character as in scrub typhus, but the plasma cells are absent and the mast cells are more numerous. The vesicle of the rash is unique in a rickettsial disease. The epithelium at the top of the vesicle shows vacuolization and some disintegration of the cells with karyorrhexis. The basal epithelium is largely intact. The corium immediately beneath the vesicle shows some migration of polymorphonuclear cells and a slight diffuse mononuclear infiltration, but in the papular portion of the eruption which forms the base of the vesicle the changes in the corium are the same as in other papular lesions."

In albino mice, intraperitoneal inoculation of infectious material results in definite signs of illness, and death frequently occurs. Mice that die or that are sacrificed when moribund show a small amount of blood-tinged peritoneal fluid, enlarged lymph nodes, an enlarged, edematous liver and a dark, engorged spleen 2 to 10 times normal size. The respiratory and intestinal tracts show no gross changes. Male guinea pigs inoculated intraperitoneally with tunica washings or infected yolk-sac tissue show redness and swelling of the scrotum with adherence of the testes to the tunica vaginalis which is thickened and markedly injected, moderately enlarged spleen and lymph nodes, occasional small areas of pneumonic consolidation and indurated cutaneous and subcutaneous nodules at the site of inoculation.

Experimental Infection, Host Range

Wild house mice (*Mus musculus*) trapped in nonendemic areas, guinea pigs, chick embryos and albino mice are susceptible. Mice inoculated intraperitoneally show ruffled fur as early as the 6th day after inoculation. Either brain or spleen tissue may be used for transfer. The peak of the disease is generally reached between the 9th and the 13th days, and death may occur at any time during this period. Male guinea pigs inoculated intraperitoneally with tunica washings first show a scrotal reaction on about the 5th day. Onset of fever may occur from the 4th to the 6th day. A febrile period, marked by remission, lasts from 3 to 5 days. Guinea pig blood is not as infectious as tunica washings and gives less consistent results on inoculation. Male guinea pigs inoculated intraperitoneally with 10 per cent yolk-sac suspensions show a short incubation period (1 or 2 days) followed by a rapid onset of high fever which is sustained without remissions for 4 or 5 days. The scrotal reaction is usually delayed until the 4th day. Chick embryos are highly susceptible to infection and show large numbers of rickettsiae both in the yolk-sac tissue and the amniotic sac. Infected yolk-sac tissue diluted 1:10 to 1:10,000 produces death of embryos in 4 to 7 days. Attempts to produce the disease in monkeys even with massive doses of infected yolk-sac suspensions have failed.

Etiology

The etiologic agent has been classified with the rickettsiae, and the name *Rickettsia akari* (Greek, mite) was proposed by Huebner et al. (1946). The organism stains poorly with methylene blue or by Gram's method but stains well with Giemsa or by Macchiavello's method, and the red-staining diplobacillary and diplococcal forms closely resemble *R. prowazekii* and *R. typhi*. *R. akari* grows in the nucleus as well as in the cytoplasm of infected yolk-sac cells—in common with the rickettsiae of the spotted fever group. During the early studies of Huebner et al., 2 strains were isolated from the blood of patients, 6

the egg to succeeding generations The hereditary transmission may continue indefinitely. Hereditary transmission probably also occurs in other species of ixodid ticks Thus no mammalian reservoir may be necessary for maintaining the infection in nature However, it is believed that wild rodents may help in disseminating the infection It has been shown experimentally that all species of ticks found in the Union of South Africa can be infected (Gear, 1950)

Control Measures

No vaccine is available at present The preventive measures are those recommended for spotted fever. avoidance as far as possible of tick-infested areas and use of all precautions to prevent tick bite Since dogs especially are readily infested with *R sanguineus*, it is advisable to free them of ticks frequently

RICKETTSIALPOX

(Synonyms—*Rickettsiose vesiculeuse* (vesicular rickettsiosis), French literature, *Gamaso-Rickettsiosis Vesiculosa* (vesicular rickettsiosis), Russian literature)

Introduction

Rickettsialpox is usually a mild febrile disease, generally characterized by an initial lesion caused by the bite of an infected mite.

History

Rickettsialpox is the name given by Huebner et al (1946) to a newly recognized rickettsial disease first reported in New York City and described independently by Sussman (1946), Shankman (1946) and Greenberg et al. (1947). Because of its clinical similarity to chickenpox, it was named rickettsialpox

Clinical Picture

The illness is characterized by an abrupt onset of chills, fever, sweats and backache, generally followed 3 or 4 days later by a rash. Usually about a week prior to the onset of fever, a firm, red papule appears at the site of a mite-bite The lesion develops into a deep-seated vesicle which ultimately shrinks and dries to form a black eschar The initial lesion persists approximately 3 or 4 weeks and, in a fully developed state, frequently resembles certain stages of a vaccinia vesicle The primary lesion (or eschar) is found chiefly on the covered parts of the body, although it may occur on the neck, the face, the arms and the dorsum of the hands. However, a primary lesion apparently has not been observed in every case Thus, it was absent in 1 of 12 cases reported by Barker (1949), in 4 of 86 cases studied by Greenberg et al. (1947), and in 6 of 35 patients observed by Rose (1949)

Rash appears in all cases and is noticed either at the onset of fever or several days later At first the lesions are maculopapular, discrete and erythematous, but after a day or so vesicles develop in the summit of the papules. They dry, forming black crusts which ultimately fall off without producing scars The rash may be scanty, moderate or abundant There is no pattern in its distribution, and it may appear first on the arms, the legs, the abdomen, the back, the face or the chest As a rule, it has not been observed on the palms and the soles, although LaBoccetta et al. (1952) have reported a suspected case of rickettsialpox in a 14-year-old white boy who showed a rash over the chest, the abdomen, the back and the extremities, including the palms and the soles. The duration of the rash varies from 2 or 3 days in mild cases to 10 days in the most severe.

Except for fever and rash, there are no unusual signs. Fever with morning remissions is often low grade at onset but usually rises rapidly to 103° or 104° F. and persists for about a week. The temperature gradually returns to normal The regional lymph nodes usually become enlarged and tender An enlarged spleen occurs in a few cases, general lymphadenopathy is uncommon Red blood cell counts and the amount of hemoglobin are normal There is a moderate leukopenia with white cells varying between 2,400 and 7,500 per cu mm. The leukopenia usually lasts only during the acute illness and disappears about 2 weeks after onset Severe headache with frontal and retro-orbital pain occurs in practically all cases Backache and general muscular soreness are common early in the disease, lassitude is always present; and photophobia is not an infrequent symptom In the United States, rickettsialpox thus far has been considered to be a mild disease, but in French equatorial Africa (Oubangui-Chari) it has

as the *vector* of the disease to man. It may

distinct stages egg, larva, protonymph, deutonymph and adult male and female The larva does not feed Blood meals, which are taken by both nymphal stages and by adults of both sexes, afford many opportunities for transmission of a pathogen during feeding by a single mite. The adult stages successfully withstand starvation for longer periods of time than do the protonymphs. As early as 1942, Ewing reported that the mite fed on human beings.

The disease has been reported to occur in other countries as well as the United States in French equatorial Africa (Oubangui-Chari) (LeGac et al 1952, LeGac, 1953); in the Soviet Union (Zdrodovskii and Golinevich, 1953; 1956b, Scientific Session Summaries, 1954) On the basis of clinical and serologic evidence, it is believed to occur in South Africa (Gear, 1954)

In French Africa, the disease has not been seen in Europeans, but only in Negroes Attempts to isolate rickettsiae from insect parasites (*Leolaps nuttali*) collected from mice (*Mus musculus*) taken in the mud walls of the huts ended in failure Likewise, no strains of *R. akari* were actually isolated from patients who were ill, but the serum of a single guinea pig inoculated with blood from one patient showed agglutinins against an American strain of *R akari* in a titer of 1 40 on the 40th day after inoculation

Within the past few years (1946-1950)

ettsiosis" (*Gamaso-rickettsiosis vesiculosa*) (Scientific Session Summaries, 1954) The disease is stated to be transmitted by several species of "gamasid" mites (*Allodermanyssus sanguineus*) found on household rodents (mice, rats) and is very similar to, if not identical with, rickettsialpox described by American workers The causative agent has been named *Rickettsia dermacentroxenus murinus* (*D murinus*) (S M Kulagin; cited above) In the U S S R , the disease was first studied and differentiated clinically by I P. Drobinskii (1949-1950; cited above). In 1950 Zhdanov and co-workers and Kulagin (cited above) isolated the causative agent from the blood of human patients and described its experimental characteristics The studies of Vasil'eva and Golinevich demonstrated that the causative agent belonged to the tick-borne spotted fever group of rickettsiae Thus the rickettsiae showed a capacity for intranuclear multiplication when grown in chick embryo pulp on semisolid agar medium

By cross complement-fixation tests the antigenic structure of *D murinus* was found to be closely related to the rickettsiae of tick-borne typhus, *R conorii* (boutonneuse fever, Black Sea strains), and to the rickettsiae of North Asian tick-borne typhus (Altai and Krasnojarsk strains) but not related to the causative rickettsiae of epidemic typhus, murine typhus or Q fever Of particular in-

tive agent of North Asian tick-borne typhus Guinea pigs, mice, rats and chick embryos are susceptible to the rickettsial agent. A readily passaged, fatal, rickettsial pneumonia is produced in mice by intranasal inoculation of infected suspension.

The clinical picture in man is similar in all respects to that described for rickettsialpox by American workers and is essentially a benign, febrile disease characterized by the presence of primary lesions (*tâche noire*) at the site of mite bite and by the formation of a peculiar rash of papular-vesiculous type.

The disease has been reported to occur in certain areas of the southern zone of the European portion of the Soviet Union, principally in certain cities of the Southern Ukraine, but apparently not in Kharkov, since mention is made of the fact that house rats

acter and shows regular focal areas of infection in certain streets, blocks and houses with infection of persons based on contact with house rodents and their ectoparasites Drobinskii (cited above) has reported that cases of vesicular rickettsiosis may be observed throughout the year, but the data presented

strains from pools of infected mites, *Allodermanyssus sanguineus* (Hirst), which is believed to be the principal vector, and 1 strain from a wild house mouse (*Mus musculus*) trapped on the premises where cases of rickettsialpox had occurred. The human, mite and mouse strains were shown to be identical (Huebner et al., 1947). Complement-fixation tests on sera from recovered guinea pigs and from human patients have shown that a very close serologic relationship exists between the rickettsiae of rickettsialpox, Rocky Mountain spotted fever and tick-borne typhus However, these infections can be differentiated by using specific antigens prepared from washed suspensions of rickettsiae. Minor cross-reactions have been noted occasionally with murine typhus antigen (Rose, 1949) Guinea pigs recovered from rickettsialpox show partial although not complete protection against both spotted fever and tick-borne typhus Rickettsialpox is serologically related to other members of the spotted-fever group but not to epidemic typhus, scrub typhus, Q fever or Colorado tick fever. Consigli et al (1957) have reported that *R akari* (McCauley strain) possesses glutamic dehydrogenase, malic dehydrogenase, ATPase and ADPase systems and is able to synthesize citrate in the presence of oxalacetate. Furthermore, they have stated that *R akari* apparently has been able to multiply after 3 serial transfers on an artifical medium in vitro

Diagnosis

Rickettsialpox shows many similarities to tick-borne typhus. However, certain differences have been observed For instance, the rash in tick-borne typhus frequently involves the palms of the hands and the soles of the feet, which rickettsialpox seldom does. The rash in rickettsialpox becomes vesicular, whereas the rash of tick-borne typhus does so only rarely. Monkeys are susceptible to tick-borne typhus but apparently not to rickettsialpox Furthermore, sera from tick-borne typhus patients show a positive Weil-Felix reaction late in the course of the disease, whereas rickettsialpox patients apparently fail to produce agglutinins for Proteus strains of organisms Rickettsialpox may be differentiated from Rocky Mountain spotted fever not only on clinical grounds but also on serologic grounds, since sera from patients with either disease usually show a higher complement-fixation titer in the presence of washed homologous rickettsial antigens

Treatment

Rose (1952) has presented the results of antibiotic therapy in 26 patients with rickettsialpox among a total of 91 cases seen at the Columbia-Presbyterian Medical Center in New York City over a period of 4½ years In untreated cases of rickettsialpox the acute febrile stage usually lasted about 1 week, the fever and the associated symptoms gradually abating over the final 2 or 3 days of illness A single case (accidental laboratory infection) that was treated with streptomycin showed no therapeutic response, since complete defervescence and relief of symptoms did not take place until 8 days after clinical onset. In contrast, patients treated with chlortetracycline (9 cases), oxytetracycline (8 cases) or chloramphenicol (8 cases) uniformly showed a dramatic improvement within 48 hours, consisting primarily of relief of headache and malaise and a fall in temperature to normal levels The symptomatic improvement was accompanied by a rapid fading of the rash and disappearance of associated manifestations of the disease such as photophobia, cough, sore throat, nausea, vomiting, chills and sweats Additional experimental tests carried out in mice definitely showed chlortetracycline and oxytetracycline to be superior to chloramphenicol, particularly when antibiotic therapy was delayed until 24 to 48 hours after infection

Epidemiology

The disease rickettsialpox was first recognized in the Borough of Queens, New York City (Shankman, 1946), but it is now believed to have occurred and to have been listed among febrile conditions of unknown etiology for a number of years previously Additional cases of rickettsialpox have now been reported from a relatively circumscribed area within the United States, including New York City, Boston, Philadelphia, Cleveland and West Hartford (Conn) (cf. Hoeprich et al., 1956). The recovery of many strains of *Rickettsia akari* from the tissues of *Allodermanyssus sanguineus*, an ectoparasite of house mice (*Mus musculus*), has established the house mouse as the *reservoir* and the mite

rise in titer by the Weil-Felix test Nine of the 12 cases showed a titer of 1 320 or greater with Proteus OX19, and in 3 of these the titer was 1 160 or greater with OX2 No significant increase in titer was seen with Proteus OXK, which is usually observed in the case of scrub typhus

Mice and guinea pigs were found to be susceptible, with the latter showing fever and a scrotal reaction similar to that produced by murine typhus Guinea pigs sacrificed at the height of fever showed a slight enlargement of the spleen and the abdominal glands and an intense hemorrhagic congestion of the tunicae Rickettsiae were readily found in the cytoplasm but not the nuclei of large endothelial cells of the tunica vaginalis Rickettsial agglutination and complement-fixation tests carried out with the sera of 5 patients and antigens of epidemic typhus, murine typhus and tick-borne typhus (both boutonneuse and South African strains) indicated no serologic relationship Funder and Jackson (1946) and Plotz et al (1946) designated the disease North Queensland tick typhus

Both groups of workers showed that the rickettsiae could be readily cultivated in the yolk sac of fertile hens' eggs and in agar-slant tissue cultures, with the latter particularly giving rich growth and showing numerous intranuclear rickettsiae in infected cells thus indicating a possible relationship of this rickettsia to other members of the spotted-fever group It is worthy of note however, that even though the agar-slant tissue cultures on the average gave a richer growth of rickettsiae than the infected yolk sac, yet the Australian workers (Funder and Jackson, 1946) still found it more practicable to prepare their antigens by the yolk-sac method of rickettsial inoculation and cultivation

These findings are entirely in line with the author's own observations on the routine mass production of rickettsial vaccines and antigens in general Funder and Jackson (1946) showed that the 2 tick typhus strains (FIK and PHS) isolated by Andrew et al (1946) were serologically similar They further reported that the sera of convalescent patients fixed complement in the presence of antigens prepared from yolk sacs infected with the

workers in that they found guinea pigs re-

covered from the PHS tick typhus strain to

Thus, the serologic data obtained by the above workers indicated no relationship between the PHS strain of rickettsiae and those of the other diseases mentioned. However, subsequent studies carried out by Lackman and Parker (1948) with the same strain of Queensland tick typhus (PHS) definitely showed this strain to belong to the spotted-fever group of diseases Complement-fixation tests carried out with soluble antigens or rickettsial suspensions of Queensland tick typhus, and guinea pig sera prepared against various rickettsial strains showed relationship to, but not identity with, other members of the spotted-fever group, such as Rocky Mountain spotted fever, tick-borne typhus (boutonneuse and South African strains), rickettsialpox and maculatum disease. No relationship was shown between Queensland tick typhus, murine typhus and Q fever

On the basis of these studies, Philip in 1950 proposed the name *Rickettsia australis* for the causative agent of Queensland tick typhus (cited by Philip, 1953). Cross-immunity tests carried out in guinea pigs by Plotz et al (1946) showed some cross-resistance between Queensland tick typhus on the one hand and murine typhus and tick-borne typhus (South African strain) on the other However, the resistance induced against heterologous organisms was related to the period of time intervening between the initial infection and the subsequent challenge, and the question was raised whether this resistance to heterologous agents was evidence of specific immunity or of an acquired cellular resistance dependent upon other factors The importance of the time element in cross-immunity tests with rickettsial agents in guinea pigs was quite properly emphasized

Fenner (1946) carried out studies to determine what animals were natural hosts of infection and to isolate the rickettsiae from ticks At 2 sites on the Atherton tableland, North Queensland, 116 native animals were trapped and their ectoparasites and blood

cyclus, Ixodes tasmani and *Haemaphysalis humerosa.* Complement-fixation tests carried

show a very marked increase in morbidity during the spring-summer period (May to August) with a maximum in May and June According to Gear (1954), most of the cases resembling rickettsialpox in South Africa have contracted their infection in the bushveld, and thus it seems likely that the reservoir of infection will be found to be one of the wild rodents and not the house mouse, and the vector may be some mite other than *Allodermanyssus sanguineous* Thus far no strains of rickettsialpox have been isolated from patients or vectors in South Africa

Control Measures

No vaccine is available, although one probably could be made readily from infected chick-embryo yolk-sac tissues Preventive measures should include the eradication of all rodents known to be actual or potential hosts for the mite vector, as well as those measures necessary for killing the mites themselves

QUEENSLAND TICK TYPHUS

In 1946, Brody of Gordonvale, North Queensland, first described a case of febrile illness which, on the basis of clinical and serologic evidence appeared to belong to the category of tick-borne typhus The illness was associated with a widespread papular rash on the trunk and the extremities (the hands and the face were unaffected), no eschar was produced, but the rash persisted throughout the illness and was still faintly visible when the patient left the hospital on the 17th day This case was distinguished by a strongly positive Weil-Felix reaction with Proteus OX2 and a lesser reaction with Proteus OX19 (1 1,280 and 1:160, respectively, on the 21st day). No causative agent was isolated, but it was pointed out that the clinical course greatly resembled that generally described for "*fièvre boutonneuse* of the Mediterranean littoral"

In the same year (1946) Andrew et al. reported the isolation of 2 strains of rickettsiae (FIK and PHS strains) from 12 patients who apparently were infected by bites of ticks on the Atherton tableland in North Queensland, Australia This land is light savannah, interspersed with dense belts of rain forest, and carries a dense marsupial and rodent population that is heavily infested with ectoparasites—mites and ticks Four species known to bite man occur in this area· *Ixodes holocyclus, Haemaphysalis bancrofti, Boophilus annulatus* and *Rhipicephalus sanguineus.* Epidemiologic evidence thus far indicates that *Ixodes holocyclus* (both larval and adult forms) in all probability are primarily responsible for transmission of the disease to man Ten of the 12 cases occurred in August and September at the time of the early spring rains when *Ixodes holocyclus* is known to be most abundant on the tableland. In 2 cases adult ticks and in 1 case a larval *Ixodes holocyclus* were actually found attached to the patients at the time of hospital admission

The incubation period of the disease was estimated to be from 7 to 10 days. The first complaint was malaise and headache, which gradually increased in intensity, was bilateral, frontal and frequently retro-orbital An eschar, similar to that seen in scrub typhus, was seen in 9 cases Adenopathy was constantly present The regional glands draining the eschar were usually considerably enlarged, painful and tender and, in 11 patients, an examination of glands remote from these areas showed enlargement which persisted for 7 to 10 days The spleen was palpable in 2 cases Fever was continuous or remittent The temperature usually subsided by lysis after an average febrile period of 7 5 days (range 2 to 12 days).

A rash appeared in 11 cases In 9 of these, an average of 3 5 days elapsed from the time of onset of symptoms (range 1 to 6 days) No particular area of the body was noted as the starting point, although the trunk was always involved when the rash was first observed Great variation in the character of the rash occurred from case to case, and the individual lesions varied in color, size, degree of elevation and density of distribution In some cases they consisted of small, scattered, erythematous macules and papules In other cases the rash consisted of large pink papules similar to those commonly seen in scrub typhus In one of the latter cases the lesions became confluent on the trunk to form large purplish blotches of generalized rash also involving the face, the scalp and the palms of the hands. In general, though, the disease was mild, and none of the cases could be considered as severe All of the cases showed a

more closely related to tick-borne typhus than to spotted fever. Guinea pigs vaccinated against Rocky Mountain spotted fever are not protected against maculatum disease. No human cases of maculatum disease have been reported thus far.

TICK-BITE RICKETTSIOSES IN INDIA

In 1917, Megaw first suggested that forms of typhus other than louse-borne occurred in India when he described his own illness that occurred 3 weeks after a tick bite as "a case of fever, resembling Brill's disease." In 1921, he correlated this illness with a number of others reported from the same general area and by analogy with Rocky Mountain spotted fever suggested that the infections were possibly transmitted by ticks From these early reports, the expression "Indian tick-typhus" came into being

The disease was characterized by a diffuse macular erythematous rash that covered the entire body, including the palms of the hands and the soles of the feet The rash became brownish red and petechial within 2 days and faded by about the 12th day when the temperature returned to normal Following Megaw's

evidence that tick-borne typhus, related to the spotted fever group of organisms, occurs in India

More recently Kalra (1952) has reported the isolation of tick-typhus strains from ticks found infected in nature He reported the isolation of a strain from *Haemaphysalis leechi var. indica* at Imphal and from *Ixodes ricinus* at Almora, recovered as well were a number of strains from adult *Rhipicephalus sanguineus* collected in Srinagar, Kashmir (Rao, 1951) Apparently, most of these strains were lost. However, a number of *Rhipicephalus sanguineus* captured on the premises of a previous patient in Srinagar, Kashmir, northern India, were sent to Dr C B Philip of the Rocky Mountain Laboratory, Hamilton, Mont., through the courtesy of Maj. S L. Kalra and Capt. K. N A Rao of the Indian Army Typhus Research Detachment. The patient had been hospitalized the year before with a typhuslike infection following tick-bite

From 5 ticks that were injected into 2 guinea pigs, a rickettsial strain (Kashmir strain) was isolated which has been maintained by means of transfer with testicular washings and minced tunica tissue for more than 50

suggestive of spotted fever in the United States.

In 1943, Topping et al reported the results of complement-fixation tests on 3 sera obtained from patients in Mysore which indicated that the causative agent was more closely related to the spotted fever than to the typhus group Seaton and Stoker (1946) examined 40 sera from cases of the typhus group of fevers in India by the complement-fixation test, using Rocky Mountain spotted fever and murine typhus rickettsial antigens Eighteen of the sera fixed complement in the presence of the murine typhus rickettsial antigens with no demonstrable cross-fixation, while 16 sera fixed complement in the presence of the Rocky Mountain spotted fever antigen, with cross-fixation in 1 case only and that to a much lower titer Of the remaining 6 sera, 5 were negative with both rickettsial antigens, while the 6th was positive with both

guinea pigs by the bites of larvae, nymphs and adults of *R. sanguineus* infected in previous stages, although some of the test animals showed mild or inapparent infections as proved by challenge with virulent material Under similar donor conditions, under which infection with Rocky Mountain spotted fever would have been expected, *D andersoni* failed to become infected These results were comparable with those obtained in experimental tests of tick transmission of tick-borne typhus strains originating in the Mediterranean area as well as in South Africa The Kashmir strain was also grown in Zinsser flask tissue cultures from which smears showed rickettsiae in the nuclei of some infected cells, thus further proving its relationship to the spotted-fever group

According to Kalra (1952) tick typhus is present in many parts of India, but its inci-

out on the sera of animals with a Queensland tick typhus antigen (FIK strain) gave positive results with 8 out of 111 serum specimens Positive results were obtained from the following marsupials: *Isoodon obesulus* (short-nosed bandicoot), *Trichosurus vulpecula johnstonii* (Johnstone's oppossum),

Atherton uromys) Presumably, these animals had been infected at some time in the past with Queensland tick typhus rickettsiae. The majority of the infected animals were collected from a localized area of rain forest where 5 of the patients mentioned by Andrew et al. (1946) presumably contracted their infection.

In 1948, Streeten et al, reported 3 cases of tick typhus from South Queensland, the clinical histories of which were identical with the descriptions given by Andrew et al. (1946) No strains of rickettsiae were isolated, so that no comparison could be made with strains derived from North Queensland tick typhus. It was pointed out, however, that they are probably closely related, if not identical, for the same tick, *Ixodes holocyclus,* is notorious in both parts of Queensland for attacking man. More recently, Neilson (1955) has reported an additional case of tick typhus from South Queensland A strain of rickettsiae was isolated from the blood of Neilson's patient by inoculating weaned mice intraperitoneally (Pope, 1955) Mice were found to be more suitable than guinea pigs for primary isolation, and no difficulty was had in maintaining the strain (JC) apparently indefinitely in mice Serologic studies carried out with convalescent serum from the patient J. C as well as with sera from mice and guinea pigs recovered from infection with the JC strain of rickettsia showed that there was no relationship to the rickettsiae of murine typhus (*R. typhi*), scrub typhus (*R tsutsugamushi*) or Q fever (*Coxiella burnetii*). However, the convalescent guinea pig serum showed fixation of complement with *R. akari,* the causative agent of rickettsialpox and a

Queensland

Since the same disease apparently has been found to occur in South Queensland as well as in North Queensland, the author agrees with Neilson (1955) that a more appropriate name for the disease is Queensland tick typhus. Should the same disease later be proved to occur in other parts of Australia, then a still more appropriate name would be Australian tick typhus

MACULATUM DISEASE

Strains of a rickettsia mildly pathogenic for laboratory animals were isolated from specimens of the Gulf Coast tick, *Amblyomma maculatum,* collected from cattle near Cleveland, Texas, in 1937. The disease was produced in guinea pigs, and the cultural characteristics and immunologic relationships of the agent were first described by Parker et al (1939) The name "maculatum disease" was given to the syndrome produced in guinea pigs. Additional isolations were made from *A. maculatum* collected in Georgia (Parker, 1940), Mississippi and Texas (Lackman, et al, 1949).

The rickettsiae grow readily in the yolk sac of the developing chick embryo The guinea pig is the laboratory animal of choice; intraperitoneal injection of testicular washings is used in making transfers The disease in the guinea pig is characterized by a mild, never fatal, infection, a short febrile period and a swollen, pinkish scrotum—not infrequently there is only fever or only a scrotal reaction without fever. Monkeys, rabbits and white rats are mildly susceptible, while the Sawatch meadow mouse is quite susceptible (Parker, 1940). There is good reciprocal cross-immunity in guinea pigs between maculatum infection, Rocky Mountain spotted fever (both Montana and Brazilian strains) and tick-borne typhus. Guinea pigs recovered from murine or louse-borne typhus are usually resistant to maculatum infection, but reverse cross-immunity does not take place, nor is there any relationship between maculatum disease and Q fever Complement-fixation studies carried out by Lackman, Parker and Gerloff (1949) confirmed the fact that maculatum disease rickettsiae belong to the spotted fever group but are antigenically different from the rickettsiae of Queensland tick typhus, tick-borne typhus (South African strain), Rocky Mountain spotted fever and rickettsialpox On the basis of the clinical picture induced in the guinea pig, Parker (1940) stated that the infection is apparently

tonitis accompanied by multiplication of rickettsiae in the mesothelial cells

In man, the incubation period is 3 to 6 days, with possible variations within the range of 2 to 7 days In many cases, the prodromal symptoms are a general indisposition, congestion, headache, muscular pains, and loss of appetite, while in other cases the disease begins without a prodromal period, with a considerable elevation in temperature Fever develops rapidly and reaches a maximum on the 3rd or 4th day of the disease, with a temperature elevation to 40° C or higher. The mean duration of fever is 8 to 10 days, usually terminating in lysis lasting 2 to 3 days The fever curve is most often of the remissive type, but occasionally the fever may be constant.

The primary lesion (*tâche noire*) is regularly observed and takes the form of a small, dense infiltrate, covered with a brown crust and surrounded by a reddish areola Histologically, it is characterized by the presence of a central wedge-shaped necrosis The primary lesion is usually accompanied by the development of regional lymphadenitis, sometimes with enlargement of the lymph nodes to the size of a pigeon's egg The localization of the primary lesion varies for example, when the patient is bitten by *D nuttalli*, the bites appear more often on the hairy part of the head, on the neck and on the shoulder area, whereas after the bite of *H concinna* the lesion is found most often on the abdomen The localization of the *tâche noire* is also determined to a considerable extent by the character of the clothing and the footwear, e g , by the degree of protection against tick-bites

The rash appears as a constant symptom of the disease, it appears sometimes by the 2nd day but usually on the 4th to the 5th days of the disease The eruption is of a polymorphic, roseoloid-papular character, with hemorrhagic transformation In many cases a copious rash covers the whole body and the extremities, in other cases the rash is less abundant, mostly localized on the chest, the back and the inner surfaces of the extremities The rash may also develop on the face, the palms and the soles The rash persists after the fever has dropped, and the pigmentation remains for a long time

TABLE 39 HOSTS OF 5 NORTH ASIAN TICKS

D nuttalli
Adults cows, sheep, horses, man
Nymphs and larvae vole, Siberian marmot (suslik), hamster, rats

D silvarum
Adults large animals both domestic and wild
Nymphs and larvae voles, mice, rats, chipmunks, hare, badger, Siberian weasel, woodcock, black bird, sparrow, greenfinch and blue magpie

D marginatus and
D pictus
Adults cattle, horses, swine, dogs and man
Nymphs and larvae narrow skulled vole, mice, hamsters, white weasel, striped squirrel, chipmunk, hawk

H concinna
Adults large animals both domestic and wild, man
Nymphs and larvae voles, mice, striped squirrels, hedgehog, greenfinch, black bird, wood cock, quail, sparrow, and man (for nymphs)

Central nervous system symptoms are generally limited to headaches, persistent and often agonizing The patients also often suffer from muscular pains as well as pains in the lumbar region However, a typhoid state and delirium are seldom observed and are not characteristic of this disease The spleen is not regularly palpable, but it may become so in the later course of a more serious illness The eyes reveal conjunctivitis and injection of the sclerae The general character of the disease is benign, with a completely favorable prognosis Relapses are not observed A positive Weil-Felix reaction to Proteus OX19 antigen appears late in the course of the disease

Specific complement-fixing antigens have been prepared from chick embryo cultures of rickettsiae Six species of ticks have been implicated in the transmission of the disease, these being *Dermacentor nuttali, D silvarum, D marginatus, D pictus, Haemaphysalis concinna*, and *H punctata*. Hosts of these ticks are given in Table 39 Their natural habitats are open areas of steppe, plains, or meadow land (*D nuttalli, D marginatus, D pictus*), hilly regions with occasional wooded shrubbery (*D silvarum*), or well-illuminated, slightly hilly, marsh land and damp places

dence is the lowest of all the typhus group of fevers. The recorded incidence of tick typhus in the literature is so meager that no statement can be made about its seasonal prevalence Surveys of the Seoni and the Chindwara forests in the Central Province showed that tick density increased during the rains, remained high during the mild winter but dropped rapidly with the approach of the hot, dry summer. It is probable that, at least in these parts, the seasonal incidence of tick-typhus follows the same course For additional comments on rickettsial diseases in India see Soman (1954).

A summation of all evidence shows that the Kashmir strain of "Indian tick-typhus" is a member of the spotted-fever group and indicates that it has a much closer relationship to the tick-borne typhus of the Mediterranean area (boutonneuse fever, causative agent, *R conorii*) than to Rocky Mountain spotted fever (causative agent, *R. rickettsii*) Additional studies are needed to determine the exact relationship of the Kashmir and other tick-typhus strains isolated in India to the other recognized rickettsial agents of the spotted-fever group.

TICK-BORNE RICKETTSIOSES *IN NORTHERN ASIA*

The available knowledge concerning rickettsial infections transmitted by ticks in northern Asia is well summarized by Zdrodovskii and Golinevich (1956a) These diseases are produced by rickettsiae of the species *Dermacentroxenus sibericus* (*Rickettsia sibiricus*) and belong to the tick-borne spotted-fever group *The clinical picture is characterized by a relatively mild, acutely febrile* course, the presence of a primary lesion (*tâche noire*), and a maculopapular rash. Various species of ixodid ticks of the genera *Dermacentor* and *Haemaphysalis*, together with certain small wild animals, constitute the reservoir of this disease. The first clinical observations were made in 1934-1936 by the Soviet investigators Mill, Antonov and Neishtadt, and Fedukovich. It was found that the disease first described in the Krasnojarsk region was the same as that found in Western, Central and Eastern Siberia and in the territories of the Far East. In addition it has been found in some localities of Central Asia and in the Mongolian Peoples Republic.

Cross-immunity experiments showed that guinea pigs that had been experimentally infected with *R. sibiricus* were fully resistant to subsequent infection with tick-borne typhus rickettsiae (boutonneuse fever, *R conorii*), isolated from dog ticks (*Rhipicephalus sanguineus*) on the coast of the Black Sea Serologic analysis of the antigenic structure showed that *R. sibiricus* is closely related to *R. conorii* and is different from the causative agents of epidemic typhus, murine typhus and Q fever. Two strains of *R. sibiricus* (Altai and Krasnojarsk strains) were shown to *multiply intranuclearly in infected epithelial* cells of the testicular membranes of guinea pigs showing periorchitis, demonstrating that these rickettsiae belong to the tick-borne spotted fever group The rickettsiae give scanty *growth in the yolk sac of the developing* chick embryo (this is the typical picture obtained with all rickettsiae of the spotted-fever group) but grow luxuriantly in minced chick embryo-agar substrate tissue cultures Rhesus monkeys infected subcutaneously or intraperitoneally show an incubation period of 3 to 4 days and fever lasting 5 to 7 days The infection is accompanied by a positive Weil-Felix reaction with Proteus OX19 antigen Male guinea pigs show considerable susceptibility, responding to infection with fever and an accompanying scrotal reaction Rabbits inoculated intraperitoneally show practically no signs of illness, but when injected intratesticularly respond with a pronounced specific orchitis. Rickettsial suspensions inoculated into the anterior chamber of the eye (rabbit) give rise to specific iridocyclitis of long duration. Intradermal inoculation of rabbits with rickettsial suspensions gives rise to *the development of a local inflammatory reaction* with subsequent necrosis. This reaction begins, on the average, after 48 hours, reaches its maximum and subsides within 9 to 10 days, with the formation of a scab Recovered rabbits show a positive Weil-Felix reaction with Proteus OX19. Rats inoculated intraperitoneally show a febrile reaction of short duration, with rickettsial peritonitis (as in boutonneuse fever), but without a prolonged maintenance of rickettsiae in the brain. Mice infected intranasally show a specific rickettsial pneumonia Intraperitoneal infection of mice produces a slight or moderately pronounced form of rickettsial peri-

causative agent has been named *Rickettsia pavlovskyi* in honor of the famed Soviet academician, E. N. Pavlovski. The morphologic features of *R. pavlovskyi* are characterized by high pleomorphism and both intracytoplasmic and intranuclear tendencies. It is claimed that the rickettsiae may be readily filtered through Berkefeld filters (porosity not stated), and that the filtrates retain their activity for more than a year at 30° C. Convalescent human sera possess the capacity to neutralize the cutaneous reaction in rabbits induced by an intracutaneous injection of infected mouse lung, rickettsial suspensions. The disease appears to be very widely spread in nature.

In the first endemic area, rickettsial strains were isolated from the blood and the organs of gophers, common weasels, field and forest mice. Rickettsial strains also were isolated from 6 groups of Ixodid ticks, *Ixodes laguri laguri*, 7 groups of larvae of the "red-bodied tick" *Trombicula autumnalis Shaw* and *Neoschoengastia*, 1 group of the "nymph red-bodied ticks" *Trombicula autumnalis* with a predominance of Neoschoengastia, 2 groups of "gamasid ticks" *Liponyssus arvicolae Zem* and *Haemogamasidae* from the nests of weasels and starlings, and 6 groups of fleas, mainly *Ctenophthalmus orientalis*. In the second endemic area, rickettsial strains were isolated from the blood and the tissues of both red and common mice (vole). Rickettsial strains were stated to be isolated also from 18 groups of "gamasid ticks" *Laelaps cleth-*

met months), 2 groups of "red-bodied ticks" *Trombicula zachvatkini*, and 3 groups of fleas, mostly *Ceratophyllus turbidus* and *Ctenophthalmus agyrtes*. Rickettsial strains were also isolated from 4 groups of *Dermacentor pictus* that were allowed to feed on guinea pigs. In the third endemic area, rickettsial strains were isolated from the blood and the organs of yellow-breasted mice, red and common voles. Rickettsial strains were also isolated from 10 groups of "gamasid ticks" containing *Laelaps agilis* (Koch), *Liponyssus talpae Zem*, and *Liponyssus arvicolae Zem*, a single group of "red-bodied ticks" *Trombicula autumnalis*, 3 groups of ixodid ticks, *Ixodes ricinus*, obtained from cows, 3 groups of fleas, of which the predominant species were *Ctenophthalmus assimilis*, *Ctenophthalmus agyrtes* and *Ctenophthalmus solutus*. In addition, it was demonstrated that rickettsiae could be transmitted from generation to generation in the ticks *Dermacentor pictus* and *Ixodes ricinus*.

MISCELLANEOUS

"Parumapertus Strains" of Spotted Fever

In 1953, Philip and Hughes reported the isolation of rickettsial strains related to the spotted fever group from lots of the "rabbit Dermacentor" tick, *D. parumapertus* collected in northern Nevada. Further studies reported more recently by Philip et al. (1955) indicate that the "*D. parumapertus* strains" apparently show a "third divergence in virulence" of the rickettsial agents recovered from North American ticks other than from the classic vectors, *D. andersoni* and *D. variabilis*. Rickettsiae representing the other two lines of divergence in virulence have been isolated from *Amblyomma maculatum*, and *Haemaphysalis leporis-palustris*, the tick vectors of which, [redacted] a rule, infest hosts other than man. Further studies will be needed to elucidate the exact relationships of these strains of rickettsial agents to one another.

(*H. concinna*). The period of greatest activity of the ticks on large animals occurs during the spring, but to a certain extent the attacks of ticks may be observed also during the following summer months It is also important to note that the adult ticks show the greatest incidence of attacking man during the spring and early summer months.

INFECTIOUS NEPHROSONEPHRITIS OF THE USSR

Recently, Korshunova (1954) has reported a disease in man, apparently rickettsial in nature, called "infectious nephrosonephritis," "kidney rickettsiosis" or "rickettsiosis with inflammation of the kidneys" Starting about 1950, the disease has been reported in 3 endemic areas of the Soviet Union, separated by great distances and covering zones of diverse topography The first area is in the southwest USSR, in the level steppes (plains), broken by low troughs of dried-up rivers and dry gullies The second area is in the central part of the Union, in a zone of mixed forest predominantly oak, with a high grassy cover, interlaced with deep ravines The third area is on the slopes of the Trans-Carpathians, in a zone of broad-leaved forest predominantly beech and oak In all 3 endemic regions the disease appears about the middle of June and continues to the middle of August with the peak in July.

The clinical illness is briefly characterized as follows a rapid onset, temperatures elevated to 38.5° to 40 0° C., flushed face and cheeks, sore throat, injection of the conjunctivae and the vessels of the sclerae, and in some cases violent vomiting. As a rule, the patients complain of pains in the back, sometimes in the abdomen. There is general malaise and great weakness with slow recovery. The urine shows albumin, erythrocytes, leukocytes and casts. The blood picture shows leukopenia in the early phases and leukocytosis in the later stages On pathologic-anatomic examination there is primarily an involvement of the kidneys, so characteristic, that by this symptom alone it is possible to diagnose the disease correctly. The configuration of the kidneys is changed, especially the right one; they are enlarged, sometimes to such an extent that the capsule is ruptured; the pyramids are dark red in color in contrast with the background of the paler cortical layer In all cases there is also noted an involvement of the anterior portion of the pituitary.

The disease has been established in guinea pigs by intraperitoneal inoculation and in mice by intracerebral and intranasal infection. Guinea pigs show an incubation period of 3 to 6 days, followed by a febrile period of 4 to 6 days with a rise in temperature to 40° C. or higher; after this, the temperature subsides rapidly or moderately. Most of the animals show a second temperature rise on the 14th to 18th days.

The pathologic picture in the guinea pig is characterized by congested lungs, liver, testes and vaginal walls. There is enlargement and inflammation of the suprarenals with necrotic centers. Frequently, the liver shows a yellowish tinge. The kidneys show "uneven inflammation" Preparations of homogenates from scrotal membranes show intracellular and extracellular rickettsiae, distinguished by marked polymorphism The disease may be maintained in guinea pigs by passage of brain or other tissues. Mice injected intracerebrally show symptoms beginning on the 8th to 10th days, marked by inactivity, shortened gait, pilo-erection and sometimes paralysis of the hind limbs The disease, whether caused by intracerebral injection or by intranasal inoculations, is always fatal in mice Mice inoculated intranasally with suspensions of infected guinea pig tissues develop a rickettsial pneumonia on the 6th to the 10th days On subsequent mouse passage, the incubation period shortens to 3 to 4 days. Homogenates of lung tissue, stained by the Romanovsky method, show great quantities of rickettsiae Rabbits inoculated intradermally, with rickettsial suspensions of infected mouse lung tissue, show a skin reaction with necrosis Rabbits injected intratesticularly develop an orchitis lasting 3 to 5 days. White rats fail to show any signs of the disease.

From the first endemic area, 8 isolates of rickettsiae were made from the blood of 20 patients, and 3 strains were isolated from the brains of 8 fatal cases In the second endemic area, 5 rickettsial strains were isolated from the blood of 10 cases studied In the third endemic area, 8 isolates of rickettsiae were made from the blood of 20 cases; 3 isolations were made from the liver, the pituitary and the cerebellum of a single fatal case. The

causative agent has been named *Rickettsia pavlovskyi* in honor of the famed Soviet academician, E N. Pavlovski. The morphologic features of *R pavlovskyi* are characterized by high pleomorphism and both intracytoplasmic and intranuclear tendencies It is claimed that the rickettsiae may be readily filtered through Berkefeld filters (porosity not stated), and that the filtrates retain their activity for more than a year at 30° C Convalescent human sera possess the capacity to neutralize the cutaneous reaction in rabbits induced by an intracutaneous injection of infected mouse lung, rickettsial suspensions The disease appears to be very widely spread in nature

In the first endemic area, rickettsial strains were isolated from the blood and the organs of gophers, common weasels, field and forest mice Rickettsial strains also were isolated from 6 groups of Ixodid ticks, *Ixodes laguri laguri*, 7 groups of larvae of the "red-bodied tick" *Trombicula autumnalis Shaw* and *Neoschoëngastia*, 1 group of the "nymph red-bodied ticks" *Trombicula autumnalis* with a predominance of Neoschoengastia, 2 groups of "gamasid ticks" *Liponyssus arvicolae Zem* and *Haemogamasidae* from the nests of weasels and starlings, and 6 groups of fleas, mainly *Ctenophthalmus orientalis* In the second endemic area, rickettsial strains were isolated from the blood and the tissues of both red and common mice (vole) Rickettsial strains were stated to be isolated also from [illegible] groups of "gamasid ticks" *Laelaps cleth-* [illegible]

fleas, mostly *Ceratophyllus turbidus* and *Ctenophthalmus agyrtis* Rickettsial strains were also isolated from 4 groups of *Dermacentor pictus* that were allowed to feed on guinea pigs In the third endemic area, rickettsial strains were isolated from the blood and the organs of yellow-breasted mice, red and common voles Rickettsial strains were also isolated from 10 groups of "gamasid ticks" containing *Laelaps agilis* (Koch); *Liponyssus talpae Zem*, and *Liponyssus arvicolae Zem*, a single group of "red-bodied ticks" *Trombicula autumnalis*, 3 groups of ixodid ticks, *Ixodes ricinus*, obtained from cows, 3 groups of fleas, of which the predominant species were *Ctenophthalmus assimilis*, *Ctenophthalmus agyrtes* and *Ctenophthalmus solutus*. In addition, it was demonstrated that rickettsiae could be transmitted from generation to generation in the ticks *Dermacentor pictus* and *Ixodes ricinus*.

Scrub Typhus

(SYNONYMS. Tsutsugamushi disease, mite-borne typhus, Japanese river fever, tropical typhus, rural typhus)

INTRODUCTION

Scrub typhus is an infectious disease caused by *Rickettsia tsutsugamushi* and characterized by sudden onset, fever of about 2 weeks' duration and a cutaneous rash which appears on approximately the 5th day The disease is transmitted by certain mites, and an eschar usually develops at the site of attachment of the "chigger " Patients with scrub typhus generally develop agglutinins against the OX-K strain of proteus bacillus Specific antibiotic therapy controls scrub typhus

HISTORY

Scrub typhus was described almost 150 years ago in Japan, and during the past 75 years has been studied assiduously by investigators of that country who discovered the vector, the etiologic agent and the rodent reservoir (cf Kawamura, 1926, Sasa, 1954) Gradually, the disease was recognized in other areas and now is known to be widespread in the roughly triangular region bounded by Japan, India and Australia (Blake et al, 1945) During World War II scrub typhus was of considerable military importance to both Allied and Japanese forces operating in the Southwest Pacific area and in the China-Burma-India Theater. Approximately 18,000 cases occurred among Allied soldiers, and in some instances the explosive outbreaks were devastating For example, 403 men in an American regiment developed the disease between the 6th and the 20th days after landing at Sansapor, moreover, the attack rate during the 2nd week at Sansapor reached 900 cases per 1,000 troops per year The fatality rates varied in epidemics in different areas, thus among the 6,685 U S Army personnel afflicted with scrub typhus, the mortality rates were as low as 0 6 per cent in some regions and as high as 35 3 per cent in others Effective measures for controlling the mite vector were developed by investigators in America and the British Commonwealth When these were applied, scrub typhus ceased to be a disease of great military importance (Philip, 1948, Fairley, 1951).

CLINICAL PICTURE

Following an incubation period of from 6 to 21 days, generally 10 to 12, illness begins suddenly with fever, chilliness, severe headache, conjunctival injection and moderate generalized lymphadenopathy. The primary lesion or eschar is found in the majority of Caucasians but in few Asiatics It occurs at sites where skin surfaces meet or clothes bind, viz, axilla and waist At the onset of fever the eschar is an indurated erythematous lesion about 1 cm in diameter surmounted by a multiloculated vesicle Within a few days the vesicle ulcerates, and the area is cov-

ered by a black scab; the regional lymph nodes become particularly prominent. The fever increases progressively during the first week of the disease, generally reaching 104° or 105° F. The pulse rate during this period is relatively slow, being 70 to 100. A red macular rash appears on the trunk between the 5th and the 8th days and may extend to the arms and the legs. The macular eruption usually persists for several days but may become maculopapular; contrariwise, it may disappear at times within a few hours.

During the first week of fever, cough is commonly present Physical and roentgenographic evidence of pneumonitis occurs frequently; Ahlm and Lipshutz (1944) observed the former in 67 per cent and the latter in 20 per cent of 70 patients

The temperature remains elevated during the 2nd week in patients who do not receive specific therapy Headache may abate somewhat after the 7th day, but apathy continues, and some deafness is commonly present. Certain patients develop additional signs of involvement of the central nervous system, for example, delirium, stupor and muscular twitching In the more severely affected patients the pulse rate increases to 120 or 140, and the systolic blood pressure may fall below 100 Frank signs of pneumonia or of circulatory failure develop in some patients Toward the end of the 2nd week or the beginning of the 3rd, the temperature of the untreated patient who is destined to recover falls by lysis over a period of several days With the reduction in fever, the pulse rate and blood pressure return to normal, the eschar is practically healed, and the spleen is no longer palpable if it had been felt during the febrile period Convalescence is generally protracted in those in whom the disease has run its full course Sequelae in the form of nervous or psychiatric difficulties were frequent among military patients, it is probable that the rigorous campaigns and intercurrent [illegible] con- [illegible] ne [illegible] d in some of the patients, might proceed to permanent damage of the heart has been overemphasized. When specific antibiotic therapy is employed during the 1st week of illness complications and sequelae are avoided, and convalescence is short

Death, when it occurs, supervenes about the end of the 2nd week and is attributable in approximately equal numbers of cases to secondary bacterial pneumonia, encephalitis or circulatory failure. The mortality varies from 1 to 60 per cent in different geographic areas and different populations. Since the introduction of specific antibiotic therapy in 1948, the picture has changed radically, and now the mortality approaches zero

Second attacks of scrub typhus are not uncommon and may occur in exposed persons within a few years after the initial illness Observations on naturally acquired disease have been augmented by studies on volunteers (Smadel et al, 1950b). Antigenic differences in strains of *R. tsutsugamushi* play an important role in susceptibility to reinfection Persons recovered from illness caused by one strain are resistant to this strain for a number of years and to heterologous strains for some months. However, the majority of such persons are susceptible to infection with heterologous strains 1 to 2 years after recovery. In some patients *R. tsutsugamushi* persists for many months after apparent recovery. This organism was isolated from a lymph node removed from one individual more than a year after infection, but similar attempts in 11 other instances yielded negative results (Smadel et al., 1952). The occasional person who is immune to a heterologous strain some years after a first attack may be one in whose tissues rickettsiae persisted and constantly stimulated the immune mechanism Recurrent scrub typhus analogous to Brill-Zinsser disease, which is a recurrence of epidemic typhus years after the original disease (cf. Chap 42), has not been recognized. However, the demonstrated persistence of *R. tsutsugamushi* in some recovered patients sets the stage for such a possibility and warrants a continuing search for late recurrences of scrub typhus.

There is no specific blood picture in scrub typhus. The leukocyte count remains essentially within the normal range unless secondary bacterial infection occurs. Anemia is rarely observed. Plasma proteins may be lowered slightly during the febrile illness If this occurs, the proportionately greater decrease

in albumin content of the plasma may produce a reversal of the albumin-globulin ratio Hypochloremia often develops late in the febrile stage as a result of inadequate salt intake and excessive sweating Certain patients with hepatic impairment show a decrease in plasma fibrinogen and an elevated icteric index.

PATHOLOGIC PICTURE

Changes observed at necropsy are not striking. Usually the eschar is found, but no rash

a superimposed, secondary bronchopneumonia The spleen and lymph nodes are enlarged

Microscopic examination brings out the fact that here, as in other rickettsial diseases, the vascular tree is primarily affected, showing a disseminated focal vasculitis and a perivasculitis of the smaller vessels consisting of accumulations of monocytes, plasma cells and lymphocytes These lesions are less severe than in epidemic typhus, furthermore, the necrosis and inflammatory reaction of the vessel wall, so characteristic of spotted fever, if present, are limited to the eschar. Vascular changes with resultant lesions in adjacent parenchymatous tissue are most conspicuous in heart, lung, brain and kidney Thus, an acute, nonsuppurative myocarditis of focal and diffuse distribution and of varying intensity is characteristically present Interstitial pneumonitis occurs in practically all fatal cases The lesions in the brain may consist of a few vascular and perivascular reactions such as are found throughout the body In certain instances, however, a true lymphocytic meningitis and an encephalitis with perivascular cuffing and formation of glial nodules occur The spleen and the lymph nodes display similar changes with infiltra-

are associated with damage to adjacent nephrons

EXPERIMENTAL INFECTION, HOST RANGE

The host range of *R tsutsugamushi* is broad, several species of mites, many species of rodents (cf. Epidemiology), and man are infected in nature, and a number of the common laboratory animals are susceptible White mice are the animals of choice for most laboratory studies of *R. tsutsugamushi.* Seven or 8 days after intraperitoneal inoculation of highly infectious material the mouse appears sick; during the next few days the abdomen swells, subcutaneous edema of the abdominal wall may appear, dyspnea develops, and death ensues. At necropsy, in addition to subcutaneous edema, lymphadenitis is apparent when the skin is reflected, the peritoneal cavity contains several cubic centimeters of serofibrinous exudate, and the surfaces are injected; finally, the spleen is enlarged and usually is coated with flecks of fibrinous ex-

ettsiae can be found in impression smears of any of the involved tissues but are demonstrated most readily in stained smears prepared from the surface of the spleen or the peritoneum. Blood, exudates and all tissues are infectious Suspensions of splenic tissue from mice infected with one of the typical laboratory strains of *R tsutsugamushi* usually have a lethal titer of about 10^{-7} when inoculated into mice by the intraperitoneal route, the titer of the blood from such animals is about 10^{-5}. Mice become infected with scrub typhus following inoculation by the subcutaneous, the intranasal, or the intravenous route, but the resultant disease differs somewhat from that described above For example, the lethal titer of a suspension of rickettsiae may be 10^{-7} when tested intraperitoneally but only 10^{-2} on subcutaneous inoculation; nevertheless, a 10^{-5} dilution of the same suspension administered subcutaneously induces an inapparent infection which is followed by immunity. The intravenous or intranasal inoculation of mice with suspensions rich in organisms results in their death in 4 to 5 days with hemorrhagic lesions in their lungs, suspensions of such pulmonary tissue have titers of 10^{-8} to 10^{-9}. Strains of *R. tsutsugamushi* vary widely in their virulence for mice; with some the minimal lethal dose and the minimal infectious dose are practically identical when the intraperitoneal route is used, while with others the lethal dose may

ered by a black scab; the regional lymph nodes become particularly prominent. The fever increases progressively during the first week of the disease, generally reaching 104° or 105° F. The pulse rate during this period is relatively slow, being 70 to 100 A red macular rash appears on the trunk between the 5th and the 8th days and may extend to the arms and the legs The macular eruption usually persists for several days but may become maculopapular, contrariwise, it may disappear at times within a few hours

During the first week of fever, cough is commonly present. Physical and roentgenographic evidence of pneumonitis occurs frequently, Ahlm and Lipshutz (1944) observed the former in 67 per cent and the latter in 20 per cent of 70 patients

The temperature remains elevated during the 2nd week in patients who do not receive specific therapy. Headache may abate somewhat after the 7th day, but apathy continues, and some deafness is commonly present. Certain patients develop additional signs of involvement of the central nervous system, for example, delirium, stupor and muscular twitching. In the more severely affected patients the pulse rate increases to 120 or 140, and the systolic blood pressure may fall below 100. Frank signs of pneumonia or of circulatory failure develop in some patients Toward the end of the 2nd week or the beginning of the 3rd, the temperature of the untreated patient who is destined to recover falls by lysis over a period of several days With the reduction in fever, the pulse rate and blood pressure return to normal, the eschar is practically healed, and the spleen is no longer palpable if it had been felt during the febrile period Convalescence is generally protracted in those in whom the disease has run its full course Sequelae in the form of nervous or psychiatric difficulties were frequent among military patients, it is probable that the rigorous campaigns and intercurrent diseases which accompanied scrub typhus contributed materially to this high incidence The possibility that myocarditis, which occurred in some of the patients, might proceed to permanent damage of the heart has been overemphasized When specific antibiotic therapy is employed during the 1st week of illness complications and sequelae are avoided, and convalescence is short.

Death, when it occurs, supervenes about the end of the 2nd week and is attributable in approximately equal numbers of cases to secondary bacterial pneumonia, encephalitis or circulatory failure The mortality varies from 1 to 60 per cent in different geographic areas and different populations. Since the introduction of specific antibiotic therapy in 1948, the picture has changed radically, and now the mortality approaches zero.

Second attacks of scrub typhus are not uncommon and may occur in exposed persons within a few years after the initial illness Observations on naturally acquired disease have been augmented by studies on volunteers (Smadel et al., 1950b) Antigenic differences in strains of *R. tsutsugamushi* play an important role in susceptibility to reinfection Persons recovered from illness caused by one strain are resistant to this strain for a number of years and to heterologous strains for some months However, the majority of such persons are susceptible to infection with heterologous strains 1 to 2 years after recovery. In some patients *R. tsutsugamushi* persists for many months after apparent recovery. This organism was isolated from a lymph node removed from one individual more than a year after infection, but similar attempts in 11 other instances yielded negative results (Smadel et al, 1952). The occasional person who is immune to a heterologous strain some years after a first attack may be one in whose tissues rickettsiae persisted and constantly stimulated the immune mechanism Recurrent scrub typhus analogous to Brill-Zinsser disease, which is a recurrence of epidemic typhus years after the original disease (cf. Chap 42), has not been recognized. However, the demonstrated persistence of *R tsutsugamushi* in some recovered patients sets the stage for such a possibility and warrants a continuing search for late recurrences of scrub typhus

There is no specific blood picture in scrub typhus. The leukocyte count remains essentially within the normal range unless secondary bacterial infection occurs. Anemia is rarely observed Plasma proteins may be lowered slightly during the febrile illness If this occurs, the proportionately greater decrease

FIG 131 Electronmicrograph of a thin section of an MB tissue culture cell infected with *R tsutsugamushi* (×40,000) The rickettsiae appear as large rodlike structures in a portion of the cytoplasm which contains normal endoplasmic reticulum and organelles The external limiting membranes of the rickettsiae are clearly discernible, as are granular structures within the organism (Prepared by S L Wissig and L G Caro by methods described in Wissig, et al, 1956)

strain of *R tsutsugamushi* are protected from disease (Topping, 1945) The neutralization technic has been useful in studies on the antigenic variations in different strains of *R tsutsugamushi* (Bell et al, 1946, Bennett et al, 1947, Fox, 1949) The extent of the antigenic diversity of strains collected in a small area is illustrated by the experience of Miesse et al (1950) Eight strains, recovered from volunteers exposed in a field of several hundred acres and from mites collected on rodents inhabiting the field, fell into 4 serogroups, and only one of these was closely related to a strain of *R tsutsugamushi* previously characterized by means of extensive cross-neutralization tests Such antigenic heterogeneity undoubtedly contributes to the susceptibility of human beings to second attacks of scrub typhus as well as to the difficulties encountered in preparing a vaccine which will protect man against exposure under field conditions (see below)

A toxin is associated with the organism of scrub typhus (Smadel et al, 1946a, Cox, 1951), its properties are similar to those of other rickettsial toxins (cf Chap. 10). Embryonated eggs infected with certain strains of *R. tsutsugamushi* provide a material which kills mice within a few hours Antitoxin capable of neutralizing this substance appears in the sera of animals convalescent from infection with the homologous strain and in the sera of some patients However, sera drawn from animals following infection with heterologous strains of *R tsutsugamushi* may not contain antitoxin, even though homologous neutralizing and complement-fixing antibodies are present

During and after World War II intensive efforts were made to develop a vaccine for scrub typhus Several groups of investigators prepared noninfectious materials which were capable of inducing appreciable resistance in laboratory animals to infection with the homologous strain of *R. tsutsugamushi* Such vaccines were derived from infected tissue obtained from cotton rats (Fulton and Joyner, 1945), white rats (Smadel et al., 1946b), agar

be *100 to 1000* times greater than the infectious dose (Jackson and Smadel, 1951); finally, certain of the strains are rarely lethal for mice under any condition Such variations in virulence have been noted among recently isolated strains and also have been observed to develop in strains maintained in the laboratory Immune mice for use in cross protection tests are obtained most readily by treating infected animals with chloramphenicol For this, mice which have been injected by the intraperitoneal route with 100 to 1000 lethal doses of the immunizing strain are provided with drinking water containing 2.5 mg of chloramphenicol per ml for a period of 3 weeks (Jackson et al., 1957).

Rickettsia tsutsugamushi grows well in the yolk-sac tissue of embryonated eggs and in several types of tissue cultures Five- or 6-day-old chick embryos are inoculated into the yolk sac with highly infectious material and then incubated at 35° C Death occurs in 6 to 10 days without pathognomonic lesions Rickettsiae are most numerous in the yolk-sac tissue, which has an infectious titer of 10^{-8} to 10^{-9}, and are readily demonstrable in stained smears Infected yolk-sac tissue serves as seed inoculum, as a source of the toxin of scrub typhus, and as starting material for the preparation of rickettsial complement-fixing antigens

Cotton rats infected by the intranasal route and white rats injected intravenously with highly infectious inocula die in 4 to 6 days and yield lung tissue with infective titers of 10^{-8} to 10^{-9} Studies on the experimental disease in monkeys, rabbits and guinea pigs provided information of historic importance, but such animals are not employed extensively at present; in the monograph by Blake et al. (1945) these studies are reviewed, as well as early work on growth of the agent in tissue culture and the experimental disease in hamsters Several species of gerbilles (rodents native to Africa) are susceptible to infection with *R tsutsugamushi* and have proved to be useful in certain types of studies (Murray et al, 1945; Mackie et al, 1946).

ETIOLOGY

The etiologic agent of scrub typhus has the general properties of rickettsiae The obligate, intracellular, parasitic, pleomorphic micro-organisms are usually seen as small diplococcuslike structures or as short rods, with bipolar dark-staining bodies, which have a length of from 0.3 to 0 5 μ and a width of from 0 2 to 0 4 μ. The rickettsiae appear as purple structures in the cytoplasm of cells when viewed in impression smears of infected tissues stained by Giemsa's method The morphologic structure of *R. tsutsugamushi* as revealed by electronmicroscopy is similar to that of other rickettsiae, the organism has a limiting membrane enclosing protoplasmic material in which are dispersed dense granules (Wissig et al, 1956), shown in Figure 131 This rickettsia multiplies at a slow rate in comparison with viruses and bacteria; thus, it increases about 3-fold each 24 hours when growing in the MBIII strain of cultured mouse cells (Bozeman et al, 1956).

R. tsutsugamushi is relatively labile, 10 per cent suspensions of infected tissues freed of large particles by light centrifugation are rendered noninfectious within a few hours by the addition of 0 1 per cent U S P formaldehyde solution. However, the organism remains viable for long periods of time when stored at −70° C in whole tissues or suspended in various protective media (Bovarnick et al, 1950) Lyophilization under carefully controlled conditions is relatively satisfactory (Jackson and Smadel, 1951), nevertheless, transportation of a newly isolated strain from the field to a central laboratory is accomplished best by shipment of infected mice if dry-ice refrigeration is not available

Specific complement-fixing antigens of scrub typhus have been prepared from several types of infected material, namely, yolk-sac tissue, mouse lung, white rat lung and cotton rat lung Methods, in which ether extraction of undiluted ground infected yolk-sac tissue is used, have provided satisfactory scrub typhus antigens, the author prefers the procedure of Topping and Shepard, method C (1946) Such antigens are of some value in the serodiagnosis of the disease in patients (cf. Diagnosis).

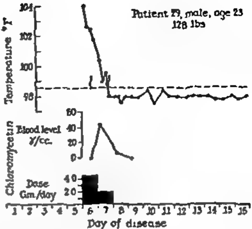
In scrub typhus, as in other viral and rickettsial diseases, convalescent animals and patients develop specific neutralizing antibodies which are detectable in their sera Mice inoculated with such sera and the homologous

as diagnostic procedures. Hence, the nonspecific Weil-Felix reaction continues to be the most useful serologic test for the diagnosis of scrub typhus in man. Agglutinins for the OX-K strain of *B. proteus* generally appear in a patient's serum by the end of the 2nd week, but none develops against the OX-19

mens of serum be obtained to demonstrate the appearance and the rise in titer of OX-K agglutinins. While a titer of 1/160 obtained with a single convalescent serum is generally regarded as significant, the result of one Weil-

in scrub typhus Indeed, in a fair number of instances patients with scrub typhus fail to develop OX-K titers of 1/160, although serial examinations may show a diagnostic 4-fold rise in the agglutinins It should be recalled that relapsing fever may evoke an OX-K response similar to that displayed in scrub typhus (Zarafonetis et al, 1946).

In evaluating the laboratory diagnostic procedures employed in scrub typhus Diercks (1951) analyzed the results obtained in 124 Malayan patients with the disease. In each instance the clinical diagnosis was confirmed by one or another of the 3 tests employed *R tsutsugamushi* was isolated from 92 per cent of the cases Although 70 per cent of the patients displayed a rise in OX-K agglutinins, only 52 per cent developed antibodies during convalescence which fixed complement in the presence of soluble antigen prepared from heavily infected yolk sacs Thus, a positive complement-fixation test is of diagnostic significance, since the reaction is specific However, a negative result is of no value in eliminating the diagnosis of scrub typhus. Doherty (1956) in a somewhat similar study found that "for the practical purpose of diagnosing scrub typhus in North Queensland the Weil-Felix reaction can be expected to detect only a little more than half the cases that occur" In the last analysis then, isolation of *R tsutsugamushi* in mice inoculated with blood from a febrile patient is the most reliable of



Rash	++ + 0

FIG 132. Response of scrub typhus Patient 29 to chloramphenicol. (Smadel, et al., 1949, Chloramphenicol [Chloromycetin] in the treatment of tsutsugamushi disease [scrub typhus], J Clin Invest. *28*, 1202)

any single test, while the Weil-Felix is the simplest to perform

TREATMENT

Chloramphenicol, chlortetracycline and oxytetracycline are specific therapeutic agents for scrub typhus Patients are rendered afebrile and almost asymptomatic in a day or two after institution of therapy Figure 132 illustrates the prompt return of temperature to normal levels within 24 hours following administration of chloramphenicol to one of the patients in the first group studied (Smadel et al, 1949)

Each of the specific antibiotics may be

tered over a period of 24 hours is adequate, but in the more seriously ill patients treatment may be required for another day or two There are no ordinary contraindications to the use of these highly effective drugs in this

tissue cultures (Plotz et al., 1946) and embryonated eggs (Bailey et al., 1948). None of the three field trials in which killed scrub typhus vaccines were employed gave encouraging results (Card and Walker, 1947; Berge et al., 1949). It is noteworthy that one of these tests was made with Malayan volunteers who were exposed by sitting in the grass in a hyperendemic area. These men had received a vaccine containing a strain of rickettsia which had been recovered earlier from infected mites collected from the exposure-area used for challenge (Smadel et al., 1950a). Such failures led the author to abandon studies on inactive scrub typhus vaccines and to turn to chemoprophylaxis of exposed persons and to the use of live vaccine combined with chemoprophylaxis to suppress clinical disease without interfering with the development of immunity. These last procedures, which were reasonably successful, are discussed below (cf Control Measures).

Chemotherapeutic studies on *R. tsutsugamushi* have been closely connected with those on other rickettsiae The steps which led to the great success in treatment of these infections have been reviewed elsewhere (Snyder, 1948; Smadel, 1949) Suffice it to say that the first significant development in the therapeutic conquest of scrub typhus began with the demonstration of Snyder et al (1942) that para-aminobenzoic acid possessed antirickettsial activity in mice infected with *R typhi*. This was followed in 1947 by the observation that chloramphenicol was highly effective in treating mice with experimental scrub typhus (Smadel and Jackson, 1947). The therapeutic value of the antibiotics chloramphenicol, chlortetracycline and oxytetracycline in patients with this disease is elaborated on below (cf. Treatment) Jackson (1951), who reviewed current experimental work and added her own comparative studies, concluded. "The general order of rickettsiostatic activity of eight substances as

cillin G, subtilin and streptomycin . . . Subtilin is more effective against *R. tsutsugamushi* than against *R. typhi* or *R. rickettsii*, while the reverse order is true for PABA." It must be emphasized that none of the clinically useful drugs is rickettsiocidal in the concentrations attained in a patient's blood; each is active because of its rickettsiostatic properties.

DIAGNOSIS

A history of exposure in an area where scrub typhus is endemic and the finding of the primary lesion (eschar) are of great assistance in the early diagnosis of the disease. Additional signs and symptoms of the malady, such as headache, conjunctival injection, fever, relative bradycardia and absence of leukocytosis, are common to many diseases which occur in scrub typhus areas, for example, other rickettsial infections, dengue, malaria, infectious hepatitis, and typhoid fever. The appearance of the skin eruption at about the end of the first week of fever is of some diagnostic assistance.

A specific diagnosis of scrub typhus may be made by recovering the causal rickettsia from the blood of a patient during the febrile period or from tissues obtained at necropsy (Smadel, 1956). A suspension of ground blood clot or of tissue is injected intraperitoneally into white mice Infected mice may die from 10 to 18 days after inoculation and show serofibrinous peritonitis and enlarged spleens. Microscopic examination of impression smears made from the surface of the spleen or the parietal peritoneum, fixed in methyl alcohol and stained by Giemsa's method, reveal the presence of minute intracellular and extracellular diplococcal organisms which have a purple color. The experimental disease is maintained by passage of bacteriologically sterile peritoneal fluid, blood, or suspensions of spleen, liver or lung Final identification of the rickettsial agent is made by cross-immunity tests performed in mice. Not all strains of *R. tsutsugamushi* are lethal for mice when first recovered from patients Therefore, in some instances examination and passage of materials from sick or apparently healthy animals may be necessary to establish the strain.

Specific serologic tests in which rickettsial materials are employed are of limited value

exacting conditions necessary for a focus result in such a sharp perimeter that Audy and Harrison (1951) have called the areas "typhus islands" Thus, in the endemic areas in Japan infection may be contracted in an uncultivated area on the river side of an embankment but not in the tilled field just inside the dike Recently, scrub typhus has been recognized among inhabitants of certain Japanese islands during the autumn and the winter when the classic vectors are absent *Trombicula scutellaris* from these islands was found infected with *R. tsutsugamushi* and on epidemiologic and ecologic grounds appears to be the vector in this region (Sasa, 1954) Elsewhere in Japan and also in Korea, *T pallida* is infected in nature and appears to be the common vector for transmission of the organism to rodents and occasionally to man (Jackson et al, 1957)

CONTROL MEASURES

The prevention of scrub typhus during military campaigns has been attained by the application of control measures aimed at the mite vector, these consist of the use of insecticides by the individual and of appropriate treatment of the terrain of endemic areas (Department of the Army Technical Bulletin TB Med 31, Scrub Typhus, 1954) These procedures cannot be expected to provide such satisfactory results when used by civilians in peacetime because of their cost and the difficulties associated with their attainment Measures for the individual are built around the use of miticidal chemicals, such as dimethyl phthalate, dibutyl phthalate, and benzyl benzoate which are applied to the clothing either by hand or by dipping In addition, insect repellent fluid containing phthalate is applied to the exposed skin The systematic use of such procedures undoubtedly reduces greatly the incidence of scrub typhus in exposed susceptible persons, but it is difficult to obtain statistically significant data on this point However, Fairley (1951) in speaking of the control program said that " within one year of its introduction in New Guinea the rate had fallen in infected areas from 36 per 1,000 to approximately 1 per 1,000" The method employed for disinfecting a camp site is as follows All vegetation is cut level with the ground and burned or hauled away. After thorough clearing, the ground usually dries sufficiently in 2 or 3 weeks to kill the mites. If the site is to be occupied before this time, the ground may be sprayed with a miticide, such as dieldrin or lindane, which will render the area free of mites for several weeks. The prevention of scrub typhus, like that of malaria, can be accomplished by control of the insect vector, however, the cost and the effort in each instance is so great that the measures cannot be employed except by an enlightened and wealthy society.

Chemoprophylaxis with chloramphenicol has been used successfully in suppressing scrub typhus in Malayan volunteers exposed in hyperinfected areas Administration of 3-Gm oral doses at weekly intervals controlled infection sufficiently to permit volunteers to remain ambulatory even though rickettsemia occurred from time to time If the drug was continued for approximately a month after the infecting mite-bite, the person remained well, but shorter periods of chemoprophylaxis were followed by clinical disease within a week after the last dose of drug (Smadel et al, 1950c).

When noninfectious scrub typhus vaccines were found in field trials to be of no value (cf Etiology), a combined procedure was studied which consisted of inoculation of volunteers with a vaccine containing living rickettsiae, together with administration of chloramphenicol according to the chemoprophylactic schedule described above The volunteers developed a primary lesion at the site of inoculation and, although ambulatory, had rickettsemia and subsequently displayed the antibody response of scrub typhus fever. Here, as in the chemoprophylactic field studies, withdrawal of the antibiotic before the 3rd week was followed by clinical disease, but prolongation into the 4th week allowed time for immunity to develop, and breakthroughs did not occur (Smadel et al, 1951) This combined procedure is cumbersome and is not yet suitable for general use, but it is applicable under special circumstances

There is no evidence of communicability of scrub typhus from man to man. Therefore,

TABLE 40 SCRUB TYPHUS PATIENTS TREATED WITH CHLORAMPHENICOL, AUREOMYCIN, TERRAMYCIN OR PARA-AMINOBENZOIC ACID

THERAPY	NUMBER OF PATIENTS	AVERAGE DURATION OF FEVER AFTER TREATMENT (hrs)	FATALITIES
CHLOR-AMPHENICOL	100	31	0
AUREOMYCIN	29	25	0
TERRAMYCIN	7	47	0
PASA	15	89	0
		DURATION OF DISEASE	
NONE	19	17 DAYS	1

(From Smadel, J. E., 1951, Present status of antibiotic therapy in viral and rickettsial disease Bull New York Acad Med, *27*, 223)

serious disease The parenteral forms of these antibiotics are indicated in rare instances in which oral medication is impossible. Table 40 summarizes the results obtained by the U S. Army Scrub Typhus Research Unit in the treatment of 170 Malayan patients who had scrub typhus. The 3 antibiotics were about equally efficacious and were superior to para-aminobenzoic acid, which had been the best drug prior to the discovery of the broad-spectrum antibiotics.

The antibiotics do not sterilize the tissues but elicit their effect by suppressing growth of the rickettsiae Ultimate recovery depends on the development of immunity by the patient. The suppressive effect of the 24-hour regimens mentioned earlier lasts for about 1 week. Immunity begins to develop late in the 2nd week of illness and gains the ascendency over the agent on about the 14th day Hence, relapses are practically never seen in patients in whom treatment is begun on the 7th day of disease or later. On the other hand, recrudescence of disease is noted in about half the patients started on the short course of therapy on the 4th to the 6th day of illness and in about three quarters of those given specific antibiotic on the 2nd day after onset Relapses respond promptly to another course of 3 to 5 Gm. of antibiotic. Moreover, they can be prevented, in those patients who [illegible] be expected to relapse, by administer[illegible] single 3-Gm. dose of antibiotic on the 6t[illegible] after termination of the original cour[illegible] therapy (Smadel et al., 1950a).

Severely ill patients, who do not re[illegible] specific therapy until late in the disease, still require the general supportive mea[illegible] and good nursing care which were so in[illegible]tant prior to the introduction of the b[illegible] spectrum antibiotics. Penicillin is of no [illegible] in uncomplicated scrub typhus, and su[illegible]amides are contraindicated Patients w[illegible] disease has been terminated by therapy *ing the 1st week* after onset enjoy a r[illegible] convalescence and may return to seden[illegible] occupations within 10 days to 2 weeks a[illegible] becoming afebrile. Those with a more [illegible]tracted illness should be permitted a lo[illegible] convalescence

EPIDEMIOLOGY

Scrub typhus occurs throughout many [illegible] the islands, coastal and river areas of east Asia, as well as in India, southeast Asia [illegible] northern Australia (for references cf Ja[illegible]son et al, 1957). The disease is transmit[illegible] by the tiny larvae of several species of mit[illegible] These chiggers, after attachment to the sk[illegible] obtain a meal of tissue juices, in the course feeding they may acquire infection from [illegible] host or transmit rickettsiae to the vertebra[illegible]

The ecology of scrub typhus througho[illegible] most of the wide geographic distribution [illegible] the disease is the classic pattern elucidat[illegible] during the early part of this century by t[illegible] Japanese scientists in the Niigata prefectu[illegible] (Kawamura, 1926, Mackie et al, 1946, Au[illegible] and Harrison, 1951). This pattern encom[illegible]passes the cyclic maintenance in nature of *[illegible] tsutsugamushi* by means of small rodents a[illegible] *Trombicula akamushi* and *T deliensis* wit[illegible] transmission to man during periods of chigg[illegible] abundance, i.e, summer in temperate area[illegible] and the rainy season in the tropics Th[illegible] transovarial transmission of rickettsiae i[illegible] these acarines facilitates maintenance of th[illegible] agent in nature, since the mite serves both a[illegible] vector and reservoir Various types of terrai[illegible] may serve as endemic areas, the commo[illegible] features of a focus are a suitable rodent population, adequate ground moisture favorable to the specific mite vectors, and the occurrence of *R. tsutsugamushi* in hosts of the area The[illegible]

vealed the rickettsia to have a cosmopolitan distribution, its presence having been reported from 23 countries A more recent survey by Kaplan and Bertagna (1955) showed the rickettsia to be present in 51 countries on 5 continents Certain areas, e g , New Zealand, Sweden, Norway, Finland, Denmark, the Netherlands and Ireland, apparently are still free of Q fever

CLINICAL PICTURE

The incubation period is generally stated to range from 2 to 4 weeks and to average about 18 to 21 days (cf Lennette, 1956) However, studies on experimental Q fever in man showed that the incubation period in individuals infected by the respiratory route with the equivalent of one guinea pig inhalatory ID_{50} was 17 days (Tigertt and Benenson, 1956), infection with larger doses of rickettsiae produced progressive shortening of the incubation period to as little as 9 days

The disease usually begins abruptly with fever, chills or chilly sensations, headache, myalgia and anorexia During the first few days, the physical signs may be limited to fever, which ranges from 101° to 104° F Elevated temperatures of variable degree may persist from a few days to as long as 3 months (Clark et al , 1951c), the febrile period is less than a week in about one third of the patients and less than 2 weeks in about one half of the patients Usually a temperature of 102° F is exceeded at some time during the illness, but such temperatures are uncom after the 3rd week of illness The fev remittent in type, and the daily fluctua in temperature may be of considerable m tude whether or not antipyretics are ad istered Chilly sensations are common d the early stages of the disease Frank may occur, especially during the first days, and in severe infections may occu most daily for several weeks. Severe chill usually followed by profuse sweating, w may lead to subsequent dehydration H ache is a common symptom and is acteristically severe Disorientation and fusion occur in a small proportion of pati Stiffness of the neck or the back, s enough to suggest meningeal irritatio sometimes seen Anorexia is a common plaint, and this, as well as the nausea the vomiting which may be present, contr to the marked weight loss that may n Hepatic enlargement and tenderness are in a small proportion of patients, as is cal jaundice (Clark et al , 1951c)

Symptoms referable to the upper res tory tract are uncommon and usually sist of slight coryza or sore throat or a dry cough However, cough is not a prom symptom (Clark et al , 1951c, Tigertt Benenson, 1956), it is seldom present at but may appear from about the 5th da and is usually slight, dry and nonprodu

On examination of the chest, physical ings are usually minimal or absent, ev the presence of a pneumonic process,

Q Fever

INTRODUCTION

Q fever is an acute systemic disease caused by a rickettsia (*Coxiella burnetii*, also known as *Rickettsia burneti*) and characterized by an abrupt onset with malaise, myalgia, severe headache, chilly sensations and high fever There is considerable variation in the severity and the duration of the disease An interstitial pneumonia frequently develops and, as is characteristic of other rickettsial diseases, rickettsemia occurs during the febrile phase However, Q fever, unlike other rickettsial diseases, is not accompanied by a cutaneous rash nor does it produce agglutinins against the so-called "X" strains of *Proteus vulgaris*

HISTORY

An outbreak of fever of unknown origin among abbatoir workers in Queensland, Australia, in 1935 was recognized by Derrick, 1937, to represent a new clinical entity He named the disease "Q fever", although it is sometimes referred to as "Queensland fever," this has no historical or geographic justifica-

named it *Rickettsia burneti*, after Burnet, whose studies had led to its classification as a rickettsia, Burnet and Freeman, 1937 At about the same time, Davis and Cox, 1938, isolated a filter-passing agent from ticks, *Dermacentor andersoni*, collected in the Nine Mile Creek area of Montana. The agent was subsequently classified as a rickettsia and, because of its filterability, was named *Rickettsia diaporica* by Cox, 1939. Comparative studies, Dyer, 1939; Burnet and Freeman, 1939, showed that *R. diaporica* was identical with *R. burneti* (now *Coxiella burnetii*) and thus suggested that Q fever was present in the United States Serologic surveys (Cox, 1940) showed that natural infection of man occurred in the Western United States, but the occurrence of clinically recognizable, naturally acquired disease was thought for some years to be restricted to Australia However, during the winter and the spring of 1944-1945, several outbreaks of pneumonitis, later proved to be Q fever, occurred among Allied troops in the Eastern Mediterranean area, more than 1000 cases were recorded (Robbins et al, 1946a, Commission on Acute Respiratory Diseases, 1946a) During the preceding winter, outbreaks of a disease referred to as "Balkan grippe" had occurred among "Axis" troops, an agent recovered from the blood of one of the patients by Caminopétros was later identified as *R burneti* (Commission on Acute Respiratory Diseases, 1946b) These represent the first naturally occurring outbreaks of Q fever recognized outside Australia. In 1946, outbreaks occurred in Amarillo, Texas (Cox et al, 1947) and Chicago meat-packing houses (Shepard, 1947), and in 1947 Q fever was found to be endemic in California (Shepard and Huebner, 1948). Numerous reports on Q fever appeared during the succeeding few years, and a literature survey by Berge and Lennette (1953a) re-

are seen more commonly in Q fever The lesions in atypical pneumonia consist of patchy and mottled infiltrations, whereas the most frequent lesions in Q fever are homogeneous consolidations Roentgenographically, Q fever closely resembles pneumococcal pneumonia (Jacobson et al, 1949); this is of interest in view of observations (Whittick, 1950) that the gross appearance of the consolidated lung at postmortem simulates that seen in pneumococcal lobar pneumonia but histologically is quite different.

Complications are not common As the temperature approaches normal, the patient's appetite returns, and there are no sequelae; a feeling of weakness or fatigue may be present for some weeks and, occasionally, months Severely ill patients may lose considerable weight (15 to 20 lbs) during the course of the disease, but such losses are remedied rapidly. Clark et al (1951c) emphasize that the disease may take a protracted course, and that fever lasting a month or more is seen not infrequently in persons over 40 years of age Evidence of hepatic involvement, including clinical icterus, was observed by Clark et al (1951c) in nearly one third of the individuals with a severe and protracted illness Thrombophlebitis, pleurisy, pleural effusions and leg pains have been reported as complications (Huebner et al, 1949a), but thrombophlebitis and leg pains resembling those of intermittent claudication have been the most commonly encountered sequelae (Huebner et al, 1949a, Clark et al, 1951c) Relapses may occur following apparent recovery (Lennette et al, 1948, Clark and Lennette, 1952, Huebner et al, 1949a)

The routine clinical laboratory tests are of little assistance diagnostically The red cell count and the hemoglobin level remain normal The total white cell and differential counts tend to remain within normal limits, but wide variations may occur and do not exclude Q fever from diagnostic consideration (Clark et al, 1951c) The only abnormal finding consistently encountered is an elevated sedimentation rate, the rate increases promptly with onset of clinical illness and apparently is higher in individuals with roentgenographic evidence of pulmonary involvement than in those without it (Tigertt and Benenson, 1956) A mild albuminuria is present during the febrile period The cold agglutination and the streptococcus MG agglutination tests are negative. Specific laboratory diagnosis of Q fever is discussed later in this chapter.

Studies on experimentally induced infections in man have yielded important and interesting information on the disease process Blanc et al. (1948) produced infection in man by intradermal, intramuscular or respiratory inoculation Intradermal inoculation produced a small local cutaneous lesion and a mild fever of brief duration, intramuscular inoculation produced considerable local swelling and a marked fever which persisted over several days; infections produced by these routes were, on the whole, inapparent However, inhalation of an infective aerosol produced a pneumonitis and typical symptoms of Q fever. In the experiments of Fonseca et al. (1949) inoculation by the respiratory route produced primarily inapparent infections Intradermal inoculation elicited a local cutaneous reaction and sometimes slight general symptoms Subcutaneous inoculation produced infections clinically typical of Q fever It is of interest (cf Epidemiology) that ingestion of infected material neither produced symptoms of infection nor elicited an antibody response Tigertt and Benenson (1956) showed that inhalation of infectious aerosols produces typical Q fever, that a pneumonitis is not an invariable concomitant of the disease process is indicated by their finding that only one half of the patients had evidence of pulmonary involvement on repeated roentgenographic examination It is of interest that the development of pneumonic lesions bore no relationship to the size of the infecting dose

PATHOLOGIC PICTURE

Q fever is rarely fatal The death rate is stated to be about 1 per cent or less among Caucasians and somewhat higher among the indigenous peoples of equatorial Africa (Babudieri, 1953a) Only a half dozen or so fatalities have been recorded in the literature (cf Whittick, 1950), and postmortem examinations were performed on some of these cases (cf Lillie, et al, 1941; Perrin, 1949, Whittick, 1950) In most of these cases, death was due to a diffuse pneumonia of lobar or greater extent The gross appearance of the consolidated lung closely resembles that

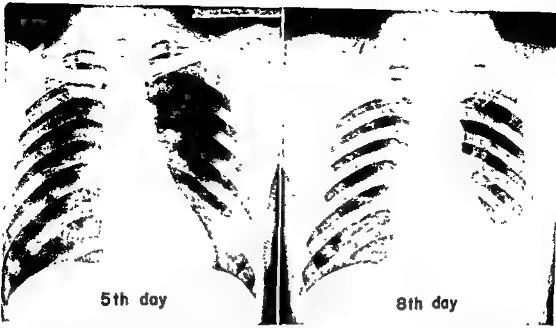

FIG 134 Roentgenogram of chest of patient with Q fever, whose chart is shown in Fig. 133. (The Commission on Acute Respiratory Diseases, 1946, A laboratory outbreak of Q fever caused by the Balkan grippe strain of *Rickettsia burneti*, Am J. Hyg *44*, 133)

elicited, they are over the area of involved lung. Careful examination may detect a few crepitant rales, a slight diminution of breath sounds, increased vocal fremitus or impaired resonance Figure 133 summates the salient data from the hospital record of an individual with a laboratory infection (Commission on Acute Respiratory Diseases, 1946c); roentgenograms of the chest of this patient are shown in Figure 134

Q fever is often regarded as a respiratory disease, because many patients develop a pneumonitis similar to that found in viral pneumonias and atypical pneumonias and demonstrable mainly by roentgenographic examination Comprehensive studies on patients involved in several laboratory outbreaks of Q fever (Hornibrook and Nelson, 1940, Spicknall et al , 1947; Robbins and Rustigian, 1946; Commission on Acute Respiratory Diseases, 1946c) revealed roentgenographic evidence of pulmonary involvement in more than 60 per cent of the individuals examined Roentgenograms have been used to detect inapparent and mild infections (Feinstein et al., 1946) but, unfortunately, pneumonitis has been so widely stressed as an integral part of the clinical picture of Q fever that its presence is sometimes considered as virtually a requisite for the establishment of a diagnosis of Q fever Q fever is a systemic disease and should not be regarded as solely a pneumonitis. In the writer's experience (Lennette and Meiklejohn, 1948; Clark et al , 1951c), roentgenographic evidence of pulmonary involvement was seen in only one third of the patients so studied. In their studies of experimental infections in man, Tigertt and Benenson (1956) likewise obtained roentgenographic evidence of pneumonia in only one half of their cases These authors also found that recognizable lesions may be present at the time of onset of fever and that the occurrence of pneumonitis was unrelated to the size of the infecting dose.

Roentgenographic changes seen in the lung are generally considered to resemble those of the viral pneumonias and the primary atypical pneumonias. However, Feinstein et al (1946) and Jacobson et al. (1949) consider Q fever to present certain distinctive roentgenographic features of its own. According to the latter workers, the hilar and vascular engorgement seen in many atypical pneumonias is absent in Q fever. Although encountered in both diseases, segmental or lobar infiltrations

in the inoculum, but the absence of such a nodule does not necessarily mean the converse. The microscopic changes seen in infected guinea pigs consist of small focal granulomata scattered throughout practically all the organs and tissues. The lesions are characterized by a vascular endotheliosis and perivascular collections of lymphocytes, less often of monocytes and fibroblasts (Lillie, 1942)

For those experimental and investigative purposes in which it is not necessary to measure the febrile response of the test animal, the hamster possesses certain definite advantages over the guinea pig Thus, the hamster is a less expensive test animal, requires less care and is much more resistant than the guinea pig to intercurrent infections In the writer's laboratory, the hamster is used almost exclusively for Q fever studies, the occurrence of infection in the inoculated test animal is determined by examining the serum for the presence of antibodies at 4 to 6 weeks after inoculation

C. burnetii is readily propagated in tissue cultures and in embryonated eggs. Embryonated eggs are inoculated into the yolk sac at 5 or 6 days of age Relatively concentrated inocula produce death of the embryo within 4 or 5 days' incubation at 35° C, and the lining cells of the sac yield a rich harvest of rickettsiae The yolk-sac tissues obtained from dead or moribund embryos provide the basic starting material for the preparation of stock rickettsial suspensions diagnostic antigens, vaccines, etc

ETIOLOGY

C burnetii is an obligate, intracellular, parasitic micro-organism It is small and pleomorphic, occurring as a diplobacillus 0 25 $\mu \times 1.5\ \mu$, a bipolar rod 0 25 $\mu \times 1.0\ \mu$ or as a lanceolate rod 0 25 $\mu \times 0.5\ \mu$ The rickettsia stains poorly by Gram's method (gram negative) but takes a purple color when stained by Giemsa's method and a red color when stained by Macchiavello's method The organisms occur as clumps and masses, usually within the cytoplasm of endothelial and serosal cells as, for example, those lining the peritoneum and also in the peritoneal exudate of mice and other animals In some preparations, the organisms may be mistaken for gram-negative bacteria because of their large size, but the same preparations will also reveal the presence of small particles with the same staining properties as the rodlike bodies The presence of very small infective particles in a homogenate of tissue infected with *C. burnetii* is revealed not only by microscopy but also by the fact that the infective property is present in filtrates of homogenates passed through collodion membranes with an average pore diameter of 400 mμ (Bengtson, 1941a) As mentioned earlier, this unusual property of filterability led to the name *Rickettsia diaporica* for this organism, Cox, 1939

Electronmicrographs show *C burnetii* to possess a limiting membrane that encloses protoplasmic material in which are interspersed granules of a denser material, comparison with other rickettsiae reveals no practical bases for the morphologic differentiation of one rickettsial species from another

C burnetii possesses properties not found in other members of the family *Rickettsiaceae*, thus, it is filterable, highly resistant to physical and chemical agents, does not elicit the so-called "X" agglutinins responsible for the Weil-Felix reaction and does not produce the cutaneous rash associated with other rickettsial diseases of man Because of these differences, Philip (1948) proposed that the Q fever agent be removed from the genus *Rickettsia* and serve as the prototype for a new genus to be known as *Coxiella* after H R Cox; the genotype was to remain the same The new name, *Coxiella burnetii* (Derrick) is listed in Bergey's *Manual of Determinative Bacteriology*, and this usage is followed here Establishment of the genus *Coxiella* has not been universally accepted, and the designation *Rickettsia burnetii* is still widely employed, especially outside the United States

C burnetii is markedly resistant to desiccation This property is important in the transmission of the disease (cf. Epidemiology), since desiccated tick tissues and tick feces, and the desiccated excreta and secretions of infected livestock contain fully viable organisms The organisms remain viable for days in water or in milk, can withstand drying at ambient room temperatures and can be preserved over long periods of time by storage in the frozen state at −20° or −70° C, and

seen in pneumococcal lobar pneumonia However, the histologic picture is quite different from that of pneumococcal pneumonia and closely resembles that seen in psittacosis and other viral pneumonias.

Microscopically, the histologic picture seen depends upon the stage in the pneumonic process at which the tissue is examined In areas of red hepatization, consolidation is uneven, and the distribution of affected alveoli is patchy and irregular The alveoli are filled with a red-staining coagulum containing a small number of neutrophilic polymorphonuclear cells and round cells in about equal proportions The round cells are chiefly mononuclear cells, although lymphocytes and plasma cells are present Red cells are sparse and seen in only an occasional alveolus An exudate similar to that in the alveoli is present in the bronchioles, and there is edema of the interlobular connective tissue

In areas of gray hepatization, the interalveolar septa are considerably thickened by infiltrations of lymphocytes, plasma cells, large mononuclear cells and neutrophils, fibroblasts, focal necrosis of some of the alveolar

nuclear cells, although numerous red cells and some neutrophils are present. The bronchioles contain a similar cellular exudate and generally show necrosis and desquamation of epithelium The subpleural and interlobular connective tissues show edema and round-cell infiltration

Whittick (1950) has demonstrated the presence of rickettsiae in large numbers in lesions in the lung, the spleen, the testes, the brain and the kidneys The organisms were found both intracellularly and free outside the cells In the lung, the spleen and the testes, the organisms were found within macrophages, and in the brain they were found within neuroglial cells In the kidneys, rickettsiae were found within the tubular epithelium, free in the lumen and also within cells of the intertubular connective tissue

EXPERIMENTAL INFECTION; HOST RANGE

The host range of *C. burnetii* is very broad, including numerous species of ticks, several insects, many species of wild and domesticated animals, and a number of birds (Weyer, 1953, Stoker and Marmion, 1955; Babudieri, 1953a; Syrůček and Raška, 1956, Raška and Syrůček, 1956). Evidence that some of these species are susceptible to natural infection has been obtained by isolation of the rickettsia or by detection of specific antibody in the blood. In other instances, susceptibility to infection has been determined (or confirmed) experimentally.

Mice, hamsters, guinea pigs and embryonated eggs have been employed in most of the investigative work on Q fever Infected mice rarely succumb to the disease, therefore, the existence of infection is generally determined by microscopic examination of the peritoneal exudate or of splenic imprints for the presence of rickettsiae Despite the lack of overt evidence of infection, the rickettsia multiplies freely, since mouse spleen tested in other species (e g , the guinea pig) gives infectivity titers of 10^{-8} or more.

Guinea pigs inoculated with *C burnetii* develop a fever, the interval between inoculation and the appearance of a febrile response depending to some extent upon the number of rickettsiae injected. Most strains of *C. burnetii*, and especially field strains at low passage levels, are not lethal for guinea pigs even when highly concentrated inocula are used However, certain strains, such as the Henzerling strain from Italy and the AD strain from California (Huebner et al , 1948) are lethal when inoculated in high concentrations, lower concentrations of rickettsiae result in infection The difference between the ID_{50} and the LD_{50} titer of such strains may be as great as 8 or 9 logarithmic units The organisms persist in the tissues of convalescent animals for many months and may be excreted in the urine over similar long periods of time (Parker and Steinhaus, 1943)

The gross pathologic changes in guinea pigs are generally limited to enlargement of the spleen, which may be from 2 to 4 times its normal size Intraperitoneal inoculation is characterized by the appearance of an exudate which covers the viscera and contains rickettsiae. Subcutaneous inoculation may elicit a firm nodule at the injection site, but such a lesion, in the author's experience, is more often called forth by laboratory passage strains than by field materials Thus, the development of such a nodule may be taken as a clue to the possible presence of rickettsiae

It thus appears that the strain to be used for the preparation of complement-fixing antigen should be chosen on the basis of the geographic area or the animal species to be tested, or both.

Apparently, the factors responsible for such differences in complement-fixing reactivity between strains are not operative in agglutination tests (Robbins et al, 1946; Stoker et al., 1955b) It seems likely that this may prove to be an important point in any future considerations of agglutination technics for diagnostic work

Animals recovered from infection with one strain develop resistance to reinfection with homologous or heterologous strains (Dyer et al, 1940, Topping et al, 1946) However, resistance is relative and may be overwhelmed by the use of potent challenge inocula; depending upon the balance between degree of resistance and size of challenge dose, reinfection may result in only a febrile response or may terminate fatally Animals recovered from infection with *C burnetii* do not acquire resistance to infection with other rickettsiae.

Some protection against infection with *C burnetii* can be conferred by administration of noninfectious vaccines prepared from animal or egg tissues rich in *C. burnetii* (Smadel et al, 1948) However, vaccination does not produce solid immunity, and the vaccinated animals are able to resist completely only a few minimal infectious doses of the homologous or heterologous strain; inoculation of larger doses results primarily in a febrile response, seldom death

DIAGNOSIS

The diagnosis of Q fever in man is established by isolation of the causal rickettsia or by demonstrating that specific antibodies against *C burnetii* have appeared, or increased in titer, in the patient's serum during the course of the illness The history and the clinical findings are generally insufficient to permit a diagnosis, but the disease should be suspected in any patient whose epidemiologic background reveals direct or indirect exposure to livestock by virtue of occupation or residence During the first few days after onset, the illness may resemble the early phases of many acute infectious diseases such as influenza, brucellosis, typhoid or paratyphoid fevers, infectious hepatitis, leptospirosis, meningitis, sandfly fever, dengue fever, malaria, other rickettsial diseases, etc Differential diagnosis in those patients who develop a pneumonitis necessitates consideration of bacterial pneumonia, psittacotic and other viral pneumonias, primary atypical pneumonia and, in certain geographic areas, coccidioidomycosis

C burnetii can be isolated from the sputum, the urine or the blood (sometimes the spinal fluid) of a patient, or from tissues obtained postmortem Since rickettsemia is present during the febrile phase of the illness, isolation is most simply accomplished by the use of blood. Guinea pigs, hamsters and embryonated eggs are the laboratory host species most commonly employed. Identification of the agent is done as follows. Guinea pigs are inoculated intraperitoneally with clinical material from the patient Animals which develop a fever are killed, the spleens are removed and passaged intraperitoneally into additional animals Several passages may be required, as rickettsiae may not be detectable in splenic smears made during the early passages When splenic imprints stained by Giemsa's or Macchiavello's method reveal the presence of rickettsiae, cross-immunity tests are performed in animals immunized to *C burnetii* and other agents A much simpler animal test is performed as follows. a group of guinea pigs is inoculated intraperitoneally with material from the patient, bled from 4 to 6 weeks later, and the individual sera are examined for the presence of specific complement-fixing or agglutinating antibodies to *C burnetii*. This method is used in the author's laboratory, the hamster being used instead of the guinea pig. Because of the very real infection hazard, not only to those actually working with the rickettsia but also to [illegible]

working area

Serologic methods are simpler and safer than isolation of the causal agent and constitute the procedures of choice in diagnostic laboratories Of the several methods for measuring antibody, the most widely employed are the agglutination test and the direct complement-fixation test The complement-fixa-

after lyophilization. According to Babudieri (1953a), it can withstand temperatures of 50° C, for at least 30 minutes and often temperatures of 60° and 70° C. for shorter periods; dried and exposed in a thin layer to irradiation by an ultraviolet lamp, it will survive for 30 minutes (Babudieri, 1953a). *C. burnetii* can withstand the action of 0.5 per cent formaldehyde for 24 hours and 0.2 per cent formaldehyde or 0.4 per cent phenol for several days.

Specific antigens for complement-fixation and agglutination tests are derived from infected yolk sacs which are rich in rickettsial content and the material of choice for this purpose. In passing, it is of interest that the first satisfactory rickettsial complement-fixing antigen prepared from yolk sac material was that for Q fever (Bengtson, 1941b).

All strains of *C. burnetii* are not equally suitable for making complement-fixing antigens. Guinea pigs infected with any strain apparently develop 2 complement-fixing antibodies. One antibody appears within 3 weeks after infection, and the other appears several weeks later, by the 9th or 10th week, the titer of the second antibody approaches the levels reached earlier by the first antibody. While most strains of *C. burnetii* contain complement-fixing antigens that react with the second antibody, certain strains appear to lack, or be relatively deficient in, the antigenic component which combines with the first antibody to appear (Robbins et al., 1946).

The Henzerling strain, isolated in Italy, was originally chosen for diagnostic work, since it contains antigens that react with both types of antibody (Robbins et al., 1946). Berge and Lennette (1953b) found that strains obtained from a variety of sources differed widely in their sensitivity as complement-fixing antigens when tested with early convalescent sera but that, in many instances, they were almost equally good as antigens when tested with sera taken some months after recovery. They also found that the so-called classic strains, viz., Dyer, Henzerling and Nine Mile, reacted equally well with both very early and very late convalescent sera. The differences in sensitivity or reactivity of an antigen with two types of antibody appears due, in some part, to the extent to which the rickettsial strain is adapted to growth in yolk-sac tissue. The studies of Stoker et al. (cf Stoker and Marmion, 1955) have shown that strains with only a few yolk-sac passages fail to react in complement-fixation tests with homologous or heterologous Q fever antisera, although the antisera react well with antigens of similar rickettsial concentration prepared from classic strains such as the Henzerling or the Nine Mile. However, after a variable number of yolk-sac passages, the new strains yield antigens which, although no richer in rickettsial content than antigens prepared from early passage material, resemble the classic strain antigens. This adaptive process has been named "phase variation" by Stoker. Antigens prepared from rickettsiae in the early stage of egg adaptation, which is called "phase 1," show no reactivity with early convalescent sera from naturally or artificially infected animals. After adaptation to the egg ("phase 2"), the same rickettsial strain yields antigens that react well with both early and late convalescent sera. (When strains in phase 2 are passaged in animals, they revert to phase 1 as shown by subcultivation of the animal passage material in the egg; several yolk-sac passages are required to reconvert the strain to phase 2.)

Factors other than phase variation are concerned in the reactivity or the sensitivity of a complement-fixing antigen. Thus, the Henzerling and the Nine Mile strains are widely used as complement-fixing antigens for diagnostic purposes since they react equally well with early and with late convalescent sera, react very well with antisera prepared against heterologous strains in guinea pigs and give good fixation with the sera of patients from areas other than the geographic point of origin of these strains. However, recent evidence indicates that even these 2 classic strains cannot be regarded as interchangeable. Thus, in at least some parts of England, the Nine Mile antigen has been found to be more sensitive than the Henzerling antigen for the detection of complement-fixing antibodies in man (Stoker et al., 1955b). The Nine Mile strain was more sensitive for the detection of antibodies in the sera of sheep from Wales, whereas the Henzerling antigen was markedly more sensitive than the Nine Mile antigen for the detection of antibodies in sheep from Kent.

to a small quantity of *C. burnetii* were not protected; 4 of 5 volunteers developed clinical symptoms after an incubation period that was prolonged for 8 or 10 days beyond that of the controls. The patients responded promptly to therapeutic administration of additional oxytetracycline, and no relapses were encountered.

The suggested antibiotic therapy for adult patients with Q fever is 2 to 3 Gm. daily of oxytetracycline, chloramphenicol or chlortetracycline administered orally; a regimen similar to the one above may be followed. Since these antibiotics are rickettsiostatic rather than rickettsiocidal, their administration should be continued for several days after the temperature has returned to normal in order to prevent relapses. If relapses occur, therapy should be reinstituted and continued again for several days after the temperature reaches normal levels.

Penicillin, streptomycin and the sulfonamides possess no therapeutic value in Q fever.

EPIDEMIOLOGY

The wide distribution of *C. burnetii* in nature—in ticks, human body lice, small wild animals, cattle, sheep, goats, birds and man—suggests that the epidemiology of Q fever in different parts of the world may vary according to the geographic and environmental factors present.

The fact that at least 22 species of tick, representing 6 genera of *Ixodid* and 2 genera of *Argasid* ticks, have been found infected (cf. Weyer, 1953; Stoker and Marmion, 1955) indicates that this arthropod plays an important role in the maintenance of the infection in nature. These ticks have come primarily from animals known to be susceptible to infection with *C. burnetii*, but it cannot be assumed that all are equally important as vectors of the disease. Thus, laboratory studies have shown that while all species that have been tested can be infected by feeding on infected animals, not all are capable of transmitting the infection. Also, although stage to stage ...

... tick generations depends upon reinfection of the arthropod host from a vertebrate host. The situation with respect to the epidemiologic role of ticks may be summarized by pointing out that while many species of ticks in various parts of the world are susceptible to infection with *C. burnetii*, and many are known to transmit the organism under laboratory conditions, little is known of the absolute or relative efficiency with which this arthropod transmits under natural conditions. As will become evident further below, the tick has little importance in the transmission of Q fever to man, and similarly it plays, in some parts of the world at least, a very minor role in the transmission of the rickettsia to domesticated livestock. Since *C. burnetii* has been found in many species of ticks, which at some stage of their life cycle feed on small wild animals, and since many of these animal hosts have been found susceptible to experimental infection, it is believed that an animal-tick-animal cycle is the basic mechanism responsible for maintenance and perpetuation of the rickettsia in nature.

Derrick's early studies incriminated cattle as a possible source of infection for man. Serologic surveys revealed that cattle were infected, and subsequently a deliberate search for an arthropod vector of the rickettsia was undertaken. The work of Derrick and his coworkers showed (Derrick, 1944, 1953) that in Australia Q fever is probably an enzootic infection of a number of small wild animals but especially of the bandicoot. About 30 per cent of the bandicoots on Moreton Island were found to possess agglutinins to *C. burnetii*, and the rickettsia was isolated both from bandicoots and from a tick, *Haemaphysalis humerosa*, with which they were heavily infested. *Ixodes holocyclus* also attacks the bandicoot, and both this species and *Haemaphysalis humerosa* ...

... tion through the mediation of a tick attacking both the bandicoot and cattle. *H. humerosa* rarely feeds on cattle and thus appeared unlikely to carry the infection from one animal species to the other. Derrick (1944) believed that infection in the bandicoot population might spill over into cattle via *Ixodes holocyclus*. This appears to be a distinct possibility since naturally infected *I. holocyclus* have been found recently on cows (Carley and Pope, 1953). Cattle ticks (*Boophilus annulatus microplus* and *Haemaphy-*

tion test has been generally preferred to the agglutination test since it is cheaper, more easy to perform and simpler to read The Henzerling and the Nine Mile strains are generally regarded as the antigens of choice, but the admonition given above (cf Etiology) to the effect that the choice of antigen may have to be based on the geographic area from which the test sera come and on the animal species from which they are obtained should be kept in mind.

The agglutination test has had a rather limited acceptance in diagnostic work but may be utilized much more widely in the future when the comparative disadvantages mentioned above are overcome Recently, micromethods using slides (Babudieri and Secchi, 1952, Babudieri, 1953b) or capillary tubes (Luoto, 1956) have been introduced Both technics are simple to perform and give reproducible results The slide agglutination method has been found, both in Babudieri's laboratory and in the author's laboratory, to be more sensitive than the complement-fixation method, perhaps this greater sensitivity may be referable to the absence or the inoperativeness of those elements which so markedly affect the sensitivity of different strains of *C burnetii* as complement-fixing antigens Precise comparative studies on the complement-fixation and the various agglutination technics are needed to evaluate the merits of the various procedures

Agglutinating antibodies appear early after the onset of illness and are demonstrable in about 50 per cent of the patients during the 1st week, the proportion of patients with agglutinins rises to 92 per cent during the 2nd week and reaches 100 per cent by the 4th week (Lennette et al, 1952b) In contrast, complement-fixing antibody appears somewhat later than does the agglutinin, it is encountered only occasionally during the 1st week of the illness, rises to 65 per cent during the 2nd week and reaches about 90 per cent at 1 month after onset Both agglutinating and complement-fixing antibodies may persist in high titer over many months

The serologic reactions obtained with Q fever antigens are highly specific, and no cross-reactions occur with any of the other rickettsial agents nor with a variety of viral agents that have been tested As is true in other viral and rickettsial infections, paired or multiple blood specimens taken during the acute and recovery, or convalescent, phases of the illness should be examined for the appearance, or rise in titer, of specific antibodies to *C. burnetii* during the course of the illness A serologic diagnosis based on these criteria rests on a much more solid footing than does one based on a so-called "diagnostic titer" determined by examination of a single blood specimen.

TREATMENT

Treatment of infected eggs with chlortetracycline (Wong and Cox, 1948), chloramphenicol (Smadel et al, 1949) and oxytetracycline (Smadel et al, 1950) has shown clearly that *C. burnetii* is highly vulnerable to the action of these antibiotics However, the efficacy of these antibiotics in the treatment of human Q fever has been difficult to evaluate because of the considerable variations in the severity and the duration of the untreated disease Several studies indicate that chlortetracycline is useful in the treatment of Q fever (Lennette et al, 1948; Clark et al, 1951b; Clark and Lennette, 1952)

Chloramphenicol (Harman, 1949; Zarafonetis and Bates, 1950) and oxytetracycline (Bickel and Plattner, 1951, Tigertt and Benenson, 1956) also have a specific therapeutic action This is clearly shown for oxytetracycline in the human volunteer studies of Tigertt and Benenson (1956) Oxytetracycline therapy was initiated within 24 hours after the onset of persistent fever in 29 volunteers who were infected by the inhalatory route The drug was usually given orally, the regimen consisting of a 3-Gm priming dose followed by 0 75 Gm. every 6 hours for a total average dose of 20 Gm over a 5- to 6-day period Cessation of symptoms occurred within 24 to 48 hours after therapy was initiated. No relapses occurred in any of the 29 clinical cases studied Prophylactic administration of oxytetracycline was studied in comparable groups of volunteers using a similar regimen of 20 Gm of oxytetracycline over a 6-day period When oxytetracycline prophylaxis was initiated late in the incubation period, clinical illness was prevented in every instance However, men placed on the same prophylactic schedule within 24 hours after exposure

(Clark et al, 1951c; 1951f). Infection was found to be widely prevalent in sheep, and although an appreciable proportion of infected animals excreted the rickettsia in the milk, such excretion was essentially confined to a very short period postpartum and would not account for the occurrence of the large number of human cases observed. Consequently, other sources of rickettsiae were searched for, and it was found that naturally infected sheep excrete *C. burnetii* not only in the milk (Lennette et al., 1949) but also in the placenta (Welsh et al., 1951, Stoker et al, 1955a), birth fluids (Abinanti et al, 1953a) and feces (Winn et al, 1953) at, or for a short time after, parturition. The placenta especially may be very heavily infected and contain as high as 10^9 hamster infective doses per Gm Luoto and Huebner (1950) also found that the organism is excreted in the placenta of the infected cow, and that the placental tissues may be very rich in rickettsial content. Experimental studies by Lennette et al (1952c), and Abinanti et al (1953b) showed that sheep can be infected by the intravenous and, much more importantly, by the respiratory route After intravenous inoculation the rickettsiae were found to localize in various organs in which they could be detected up to the end of the 6-week observation period, except for several isolated instances, no shedding of the organisms occurred via mammary gland secretions, the urine, the feces or by way of the oral or nasal secretions. Similarly, after intratracheal inoculation no remarkable excretion of rickettsiae by any of these routes was encountered, however, several of the inoculated animals lambed some months after inoculation, and the rickettsiae immediately appeared in the oral and nasal secretions and in the urine and the feces of the parturient animals Further studies show that during parturition, infective aerosols are generated and lead to demonstrable infection of the aerial environment (Welsh et al., 1957) The Northern California workers were also able to detect the presence of rickettsiae in the air of premises harboring infected cows, goats and sheep (De Lay et al, 1950, Lennette and Welsh, 1951). The results of the California studies indicate that in that area arthropods play no role in the transmission of infection among livestock or

in man may occur from primary aerosols generated during parturition of the animal. Infection may also be acquired from secondary aerosols, i e , contaminated dust, hides, fleece, etc., since desiccation of infected birth fluids and placentas as well as of other secretions or excretions gives rise to an environment in which aerosols of infective dust can be created. It is of interest that in Northern California the peak incidence of human cases occurs at the time of the lambing season, whereas in Southern California human cases

from the reproductive tract of one animal to the respiratory tract of another; infec-

tion of infected milk or colostrum, but the available evidence suggests that the respiratory route is the more important.

Man may acquire his infection by direct contact with livestock, i e , through direct exposure to infectious aerosols generated by the act of parturition or by direct exposure to

However a large proportion of cases of Q fever occurs among individuals with no history of direct or even indirect contact with livestock; such cryptic infections may occur as sporadic cases or in the form of outbreaks (cf Clark et al , 1951f) The Northern California group (Clark et al , *1951e, 1951f*) have stressed the importance of infected "micro-environments" as a source of infection in such cryptic cases. Thus, in one outbreak infections occurred predominantly among individuals with indoor pursuits, e g, attorneys, court clerks, a judge,

occupationally engaged, and that infection probably was brought to them in the form of mobile micro-environments

importance of such micro-environments is in-

salis bispinosa) may in turn acquire the rickettsia by feeding on their infected hosts. Whether cattle ticks can spread the infection through a herd is uncertain, especially in the case of *B microplus* which spends its entire life on one animal. The tissues and especially the feces of such infected cattle ticks may contaminate the hides of their hosts and thereby give rise to a potential infection hazard of man

A wild animal-tick-domestic animal association similar to that just described appears to exist in other parts of the world, e g., Morocco and Spain In Morocco the gerbil (merion rat or desert rat) *Meriones shawi* is heavily parasitized by ticks of the genus *Hyalomma*, and infected ticks of *Hyalomma spp.* have also been found on sheep, goats and cattle (Blanc and Bruneau, 1949). In Spain, *Hyalomma marginatum*, *Rhipicephalus bursa* and *R. sanguineus* have been found on livestock, and both cattle and small mammals (dormice and mountain rabbits) have been found to be infected (Pérez Gallardo et al , 1949; 1952). It thus seems possible that in certain areas, at least, the tick may serve to carry the infection outside its basic cycle in small animals to the domestic animals of man.

With rare exceptions, patients with Q fever give no history of tick-bite Early studies indicated that Q fever was an occupational disease apparently acquired by direct contact with infected meat or by inhalation of infected dust from cattle hides contaminated with infected tick tissues or tick feces. Inasmuch as *C. burnetii* remains viable in ticks over periods of many months, and since the tissues and the excreta of infected ticks contain tremendous concentrations of rickettsiae, such materials may well constitute a source of infection under some circumstances, for example, the outbreak of Q fever among stock handlers in Amarillo, Texas. Indeed, infection by the respiratory route affords the only possible, and logical, explanation of a number of outbreaks in military and civilian populations and especially of outbreaks which occurred in laboratories (Robbins et al., 1946a, Commission on Acute Respiratory Diseases, 1946c; Topping et al., 1947; Wegmann, 1948; Huebner, 1947; Kikuth and Bock, 1949; Hornibrook and Nelson, 1940).

The localized nature of some outbreaks and the tendency to affect primarily individuals coming within certain areas (e g , Army billets, houses, farms, etc.) pointed to Q fever as a "place disease." The explosive nature of other outbreaks pointed to a common source of infection for man. This was true in Italy, for example (Robbins et al., 1946a) where epidemiologic evidence ruled out person-to-person transfer, and it was not possible to incriminate food or water. The Italian outbreaks were found to be associated with animal life—birds, rodents and domestic livestock—and it was considered that these or oth[illegible]

of

wit

houses used as billets and on hay and straw used [illegible] bedding material.

Much of our information on the natural sources that give rise to such outbreaks comes from field studies in the United States. The discovery of human cases of Q fever in Southern California in 1947 led to intensive epi-

[illegible]

Los Angeles area had serologic evidence of infection, that nearly one half of the immigrant cattle coming from nonendemic areas became infected within 6 months after arrival, and that *C. burnetii* was excreted in the milk of a large proportion of the dairy cattle Since the raw milk of more than half of the dairies tested in the area contained readily demonstrable *C. burnetii* (Huebner et al , 1949a, Huebner et al , 1948) and since complement-fixing antibodies to *C burnetii* were encountered more frequently among drinkers of raw milk than among users of pasteurized milk (Bell et al , 1950), contaminated milk appeared to be a possible source of human infection However, the ingestion of raw milk as a cause of human Q fever would not explain the occurrence of the disease in a considerable proportion of individuals who did not use raw milk (Bell et al., 1950, Lennette and Clark, 1951). In addition, the studies of Fonseca et al. (1949) showed that man is

[illegible]

finding that in Northern California human cases of the disease gave a history of direct or indirect contact with sheep and goats rather than with cattle, and the milk of these former species was not utilized as a food product (Lennette et al , 1949; Lennette and Clark, 1951).

Studies in Northern California pointed to sheep as a source of infection and to the respiratory tract as a portal of entry in man

ranted However, sterilization of sputum and excreta is recommended, and precautions should be taken in the handling, or the post-mortem examination, of individuals dead of Q fever. These recommendations are based on such episodes as that described by Siegert et al (1950) in which a hospitalized patient infected 38 other individuals, including patients and members of the staff Marmion and Stoker (1950) report several cases which occurred in connection with an autopsy, and Babudieri (1953a) mentions an episode in which 16 of the 17 individuals present at the postmortem on an individual who died of Q fever were infected

Care must be exercised in other respects also, and material which can even remotely be considered as contaminated should be sterilized Thus, an outbreak of Q fever in a rendering plant was traced to the processing of discarded guinea pigs infected with *C burnetii* (Feldman et al, 1950), and infections in laundry workers have been traced to the handling of contaminated clothing received from experimental laboratories (Oliphant et al, 1949)

dicated by the fact that contaminated apparel has been incriminated epidemiologically as the source of rickettsiae in a number of human infections (Beck et al, 1949; Oliphant et al, 1949; Clark et al, 1951e, Derrick, 1953). Similarly, Q fever has occurred in wool- and hair-processing plants (Sigel et al, 1950) and the *importance of fleeces and hides in carrying the infection to the individual* is amply demonstrated by isolation of the rickettsia from sheep wool [illegible]

CONTROL MEASURES

Satisfactory control of Q fever with respect to both the individual and the community still remains to be achieved Since the large preponderance of human infections appears to be acquired through direct or indirect contact with livestock, it would appear desirable to eliminate infection from herds or flocks However, since infection in livestock is of no consequence economically, it does not seem probable that any great effort would be made by animal husbandrymen to stamp out infection among their herds of cattle or goats or flocks of sheep through the administration of specific antibiotics or through vaccination even were the latter procedures effective and feasible economically Nor does it seem likely that any effective attempts will be undertaken in the near future to confine calving, kidding or lambing operations to a restricted area which can be decontaminated after the placenta and the dejecta have been collected and disposed of appropriately Consequently, to protect those whose occupation brings them into contact, however indirect, with livestock —for example, slaughterhouse workers, rendering-plant workers, cow and goat dairy workers, sheep and goat herders and other persons exposed to infective aerosols and dusts—immunization by means of a specific vaccine would appear to be desirable Meiklejohn and Lennette (1950) reported that no cases of clinical Q fever occurred among 50 persons vaccinated in their laboratory, further evidence of a protective effect is indicated by the discovery that 6 of the 50 individuals became infected, but no overt manifestations were elicited. The studies of Tigertt and Benenson (1956) provide somewhat more direct evidence of the efficacy of Q fever vaccines Eight individuals who had received vaccine prepared from the Henzerling strain were subsequently exposed to a moderate inhalatory dose of *C. burnetii* At the time of the exposure the antibody levels of these individuals were declining; the inhalatory exposure did not result in clinical disease but did produce a rise in the declining antibody levels Other individuals were similarly exposed 9 months after their initial vaccination and were found to be resistant to infection. Even those individuals who had not developed demonstrable complement-fixing antibodies at any time after vaccination were protected against respiratory inoculation Finally, to ascertain what effect administration of vaccine during the incubation period might have on the development of the disease, 5 volunteers were given 1 ml of vaccine 24 hours after respiratory exposure Overt illness developed in only 1 of the 5 individuals and then after a prolongation of the incubation period

In areas where Q fever is enzootic in domestic livestock, milk from cows, goats and sheep should be boiled or pasteurized Pasteurization by the vat-holding method (143° F. for 30 minutes) has been found inadequate to destroy *C burnetii* (Huebner et al, 1949b, Marmion et al, 1951; Lennette et al, 1952a). The comprehensive studies of Enright et al (1957) show that while a temperature of 143° F. for 30 minutes is inadequate to eliminate viable *C. burnetii* from milk, a temperature of 145° F. for 30 minutes ensures destruction of the rickettsia On the basis of their findings, these workers recommend that the requirements for high temperature short time (HTST) pasteurization be held at the present standard, viz, 161° F for 15 seconds

The possibility of person-to-person transmission of Q fever is so small that the quarantining of patients and the employment of extensive isolation precautions are not war-

ranted However, sterilization of sputum and excreta is recommended, and precautions should be taken in the handling, or the postmortem examination, of individuals dead of Q fever These recommendations are based on such episodes as that described by Siegert et al (1950) in which a hospitalized patient infected 38 other individuals, including patients and members of the staff Marmion and Stoker (1950) report several cases which occurred in connection with an autopsy, and Babudieri (1953a) mentions an episode in which 16 of the 17 individuals present at the postmortem on an individual who died of Q fever were infected

Care must be exercised in other respects also, and material which can even remotely be considered as contaminated should be sterilized Thus, an outbreak of Q fever in a rendering plant was traced to the processing of discarded guinea pigs infected with *C burnetii* (Feldman et al, 1950), and infections in laundry workers have been traced to the handling of contaminated clothing received from experimental laboratories (Oliphant et al, 1949)

dicated by the fact that contaminated apparel has been incriminated epidemiologically as the source of rickettsiae in a number of human infections (Beck et al., 1949; Oliphant et al, 1949; Clark et al., 1951e; Derrick, 1953). Similarly, Q fever has occurred in wool- and hair-processing plants (Sigel et al, 1950) and the importance of fleeces and hides in carrying the infection to the individual is amply demonstrated by isolation of the rickettsia from sheep wool (Abinanti et al, 1955, Stoker et al, 1955a). Contaminated microenvironments explain not only the occurrence of such cases but also those which occurred in laundries, an art school, a locksmith shop (cf. Welsh et al, 1957), and among personnel handling mail bags carried in vehicles previously used for the transportation of animals, and also among persons exposed to dust from grain used as animal food (cf Stoker and Marmion, 1955)

CONTROL MEASURES

Satisfactory control of Q fever with respect to both the individual and the community still remains to be achieved Since the large preponderance of human infections appears to be acquired through direct or indirect contact with livestock, it would appear desirable to eliminate infection from herds or flocks However, since infection in livestock is of no consequence economically, it does not seem probable that any great effort would be made by animal husbandrymen to stamp out infection among their herds of cattle or goats or flocks of sheep through the administration of specific antibiotics or through vaccination even were the latter procedures effective and feasible economically Nor does it seem likely that any effective attempts will be undertaken in the near future to confine calving, kidding or lambing operations to a restricted area which can be decontaminated after the placenta and the dejecta have been collected and disposed of appropriately Consequently, to protect those whose occupation brings them into contact, however indirect, with livestock —for example, slaughterhouse workers, rendering-plant workers, cow and goat dairy workers, sheep and goat herders and other persons exposed to infective aerosols and dusts—immunization by means of a specific vaccine would appear to be desirable Meiklejohn and Lennette (1950) reported that no cases of clinical Q fever occurred among 50 persons vaccinated in their laboratory, further evidence of a protective effect is indicated by the discovery that 6 of the 50 individuals became infected, but no overt manifestations were elicited. The studies of Tigertt and Benenson (1956) provide somewhat more direct evidence of the efficacy of Q fever vaccines. Eight individuals who had received vaccine prepared from the Henzerling strain were subsequently exposed to a moderate inhalatory dose of *C burnetii* At the time of the exposure the antibody levels of these individuals were declining; the inhalatory exposure did not result in clinical disease but did produce a rise in the declining antibody levels Other individuals were similarly exposed 9 months after their initial vaccination and were found to be resistant to infection Even those individuals who had not developed demonstrable complement-fixing antibodies at any time after vaccination were protected against respiratory inoculation Finally, to ascertain what effect administration of vaccine during the incubation period might have on the development of the disease, 5 volunteers were given 1 ml of vaccine 24 hours after respiratory exposure Overt illness developed in only 1 of the 5 individuals and then after a prolongation of the incubation period

In areas where Q fever is enzootic in domestic livestock, milk from cows, goats and sheep should be boiled or pasteurized Pasteurization by the vat-holding method (143° F. for 30 minutes) has been found inadequate to destroy *C burnetii* (Huebner et al., 1949b; Marmion et al, 1951, Lennette et al, 1952a) The comprehensive studies of Enright et al. (1957) show that while a temperature of 143° F. for 30 minutes is inadequate to eliminate viable *C. burnetii* from milk, a temperature of 145° F. for 30 minutes ensures destruction of the rickettsia On the basis of their findings, these workers recommend that the requirements for high temperature short time (HTST) pasteurization be held at the present standard, viz, 161° F. for 15 seconds

The possibility of person-to-person transmission of Q fever is so small that the quarantining of patients and the employment of extensive isolation precautions are not war-

with undermined, irregular edges Eventually healing is complete without scar formation (Flaum, 1939)

The histopathologic picture of experimentally induced lesions consists of hyperkeratosis, swollen and hyperplastic cells of the malpighian layer which disintegrate to form loculated vesicles, intranuclear inclusions in cells near the vesicles, and infiltration of adjacent tissues with polymorphonuclear leukocytes The disease can be transmitted experimentally to the guinea pig by cutaneous and subcutaneous inoculation of the foot pads, and to suckling mice by intraperitoneal inoculation Necrosis of skeletal muscle occurs in young mice Rabbits, rats, mice, dogs and cats are irregularly susceptible while fowl (except ducks), ferrets and horses are usually resistant The resistance of the horse is of prime importance, for it serves to differentiate the virus of foot-and-mouth disease from that of equine vesicular stomatitis

The diameter of the virus as determined by filtration through gradocol membranes is 10 to 12 mμ, while electronmicroscopy and ultracentrifugation indicate the average particle size to be larger, 20 to 30 mμ The complement-fixing antigen measures 6 to 7 mμ The virus in tissues is fairly resistant to disinfectants, the most practicable virucidal agent is 0 5 to 2 per cent sodium hydroxide (Olitsky et al, 1928) The active agent is stable in 2 pH zones, namely, 2 5 to 3 5 and 6 5 to 10 0 It can be grown in tissue cultures only when tissue from susceptible species is used There are 7 immunologically distinct types During convalescence, human beings and lower animals produce antibodies specific for the particular strain inducing the infection

Diagnosis is accomplished by the isolation and the identification of the causal agent, and by serologic test, particularly complement-fixation There is no specific treatment Since the virus is found in the blood, saliva, urine, feces, milk and vesicular lesions of infected animals, such materials, as well as infected fodder, hair, bones, hides, meat and dairy products, play an important role in the spread of infection The boiling or pasteurizing of farm products under suspicion should be adequate for control of the disease in a human population Ruthless slaughter of susceptible hosts is the most successful method of controlling epizootics a less successful method consists of using hyperimmune serum and vaccines (Waldmann, 1938)

Following the mass cultivation of the viruses in explants of cattle tongue epithelium (Frenkel, 1950) this and other types of bovine tissue culture have been employed for studies of viral multiplication (Sellers, 1955, Cartwright et al, 1957) and for the manufacture of formaldehyde-inactivated vaccine Unfortunately, the best vaccines produce an immunity which lasts only 4 to 6 months, and repeated vaccination is necessary

NEWCASTLE DISEASE

(SYNONYMS Avian pseudoplague, avian pneumoencephalitis)

Newcastle disease (ND) is an epizootic infection of fowl characterized by viremia and signs of involvement of the respiratory, the gastro-intestinal and the central nervous systems The disease has been recognized as a distinct clinical and pathologic entity since the work of Doyle, 1927, and has been encountered in continental Europe, England, Asia, Africa and Australia It was first recognized in the United States in California as pneumoencephalitis, Beach, 1946, and is known to have reached the East coast by 1944 Beach, 1944, showed that the viruses of Newcastle disease and pneumoencephalitis are immunologically identical There is an opinion that pneumonic and nervous signs dominate the American type of infection, while respiratory and gastro-intestinal signs are the most obvious in the Old World type, Brandly et al, 1946a The malady occasionally attacks human beings who handle infected fowl or work with the ND virus, manifesting itself chiefly as a superficial conjunctivitis At least 10 proved and 17 suspected cases have been reported

Newcastle disease in fowl usually has an incubation period of 4 to 11 days Onset is sudden with drowsiness, rapid respiration and fever Then, diarrhea sets in, brown fluid or saliva drools from the beak, a thick mucous discharge from the nose appears, and respiratory distress, cyanosis and petechiae of the wattles and the comb occur Opisthotonos, convulsions, ascending paresis and abnormal movements have also been observed Death ensues, usually on the 6th to the 8th day, in

Infections of Minor Importance

This chapter is concerned with several virus diseases with well-characterized agents as well as certain infectious processes in which a viral etiology is only presumptive Certain of them e g , trench fever and viral gastroenteritis, usually occur as epidemics Others represent diseases of animals in which human infection is accidental Still others, like warts, are extremely common in man but rarely produce serious illness In a few instances, as encephalitis lethargica, diseases are discussed which, although major medical problems at one time, are now almost extinct

A *Viral Diseases With Primary Reservoir in Nonhuman Hosts*
 1 Foot-and-Mouth Disease
 2 Newcastle Disease
 3 Equine Infectious Anemia
 4 Cat-Scratch Disease
 5 Lymphocytic Choriomeningitis
 6. Encephalomyocarditis

B *Viral Disease With Reservoir Unknown*
 1 Warts. Verrucae
 2 Molluscum Contagiosum
 3 Epidemic Viral Gastroenteritis
 4. Salivary Gland Virus Infection

C *Diseases of Presumptive Viral or Rickettsial Origin*
 1. Infectious Polyneuritis
 2. Hemorrhagic Meningoencephalitis
 3. Durand's Disease
 4 Encephalitis Lethargica
 5 Postinfection (Demyelinating) Encephalitis
 6 Trench Fever

FOOT-AND-MOUTH DISEASE

(SYNONYMS *Fievre aphtheuse, Maul-und-Klauenseuche,* aphthous fever, epizootic *aphthae, epizootic stomatitis*)

Foot-and-mouth disease is a highly contagious infection of cloven-footed animals, especially of cattle, pigs, sheep and goats, and is rarely transmitted to human beings, who become infected by ingestion of virus-contaminated food, by handling the active agent, or through contact with affected animals Since epizootics of the disease are rare in the United States, the malady in human beings in this country is uncommon. However, the disease is now endemic in Mexico and Canada

The disease in lower animals is characterized by fever, salivation and the appearance of large, coalescing vesicles in the mucous membranes of the mouth, the tongue and the lips, and in the skin of the hoofs, dewclaws, interdigital areas and the udder The disease in human beings manifests itself, after an incubation period of 2 to 18 days, by fever, salivation, vesicles in the mucous membranes of the mouth, the pharynx, the lips and the tongue and in the skin of the soles, the palms, the digits and the interdigital areas Within a few days, the vesicles rupture, leaving ulcers

with undermined, irregular edges Eventually healing is complete without scar formation (Flaum, 1939)

The histopathologic picture of experimentally induced lesions consists of hyperkeratosis, swollen and hyperplastic cells of the malpighian layer which disintegrate to form loculated vesicles, intranuclear inclusions in cells near the vesicles, and infiltration of adjacent tissues with polymorphonuclear leukocytes The disease can be transmitted experimentally to the guinea pig by cutaneous and subcutaneous inoculation of the foot pads, and to suckling mice by intraperitoneal inoculation Necrosis of skeletal muscle occurs in young mice Rabbits, rats, mice, dogs and cats are irregularly susceptible while fowl (except ducks), ferrets and horses are usually resistant The resistance of the horse is of prime importance, for it serves to differentiate the virus of foot-and-mouth disease from that of equine vesicular stomatitis

The diameter of the virus as determined by filtration through gradocol membranes is 10 to 12 mμ, while electronmicroscopy and ultracentrifugation indicate the average particle size to be larger, 20 to 30 mμ The complement-fixing antigen measures 6 to 7 mμ The virus in tissues is fairly resistant to disinfectants, the most practicable virucidal agent is 0 5 to 2 per cent sodium hydroxide (Olitsky et al , 1928) The active agent is stable in 2 pH zones, namely, 2 5 to 3 5 and 6 5 to 10 0 It can be grown in tissue cultures only when tissue from susceptible species is used There are 7 immunologically distinct types During convalescence, human beings and lower animals produce antibodies specific for the particular strain inducing the infection

Diagnosis is accomplished by the isolation and the identification of the causal agent, and by serologic test, particularly complement-fixation There is no specific treatment Since the virus is found in the blood, saliva, urine feces, milk and vesicular lesions of infected animals, such materials, as well as infected fodder, hair, bones, hides, meat and dairy products, play an important role in the spread of infection The boiling or pasteurizing of farm products under suspicion should be adequate for control of the disease in a human population Ruthless slaughter of susceptible hosts is the most successful method of controlling epizootics a less successful method consists of using hyperimmune serum and vaccines (Waldmann 1938)

Following the mass cultivation of the viruses in explants of cattle tongue epithelium (Frenkel, 1950) this and other types of bovine tissue culture have been employed for studies of viral multiplication (Sellers, 1955, Cartwright et al , 1957) and for the manufacture of formaldehyde-inactivated vaccine. Unfortunately, the best vaccines produce an immunity which lasts only 4 to 6 months, and repeated vaccination is necessary.

NEWCASTLE DISEASE

(SYNONYMS Avian pseudoplague, avian pneumoencephalitis)

Newcastle disease (ND) is an epizootic infection of fowl characterized by viremia and signs of involvement of the respiratory, the gastro-intestinal and the central nervous systems The disease has been recognized as a distinct clinical and pathologic entity since the work of Doyle, 1927 and has been encountered in continental Europe, England, Asia, Africa and Australia It was first recognized in the United States in California as pneumoencephalitis Beach, 1946, and is known to have reached the East coast by 1944 Beach, 1944, showed that the viruses of Newcastle disease and pneumoencephalitis are immunologically identical There is an opinion that pneumonic and nervous signs dominate the American type of infection, while respiratory and gastro-intestinal signs are the most obvious in the Old World type, Brandly et al , 1946a The malady occasionally attacks human beings who handle infected fowl or work with the ND virus, manifesting itself chiefly as a superficial conjunctivitis At least 10 proved and 17 suspected cases have been reported

Newcastle disease in fowl usually has an incubation period of 4 to 11 days Onset is sudden with drowsiness, rapid respiration and fever Then, diarrhea sets in brown fluid or saliva drools from the beak, a thick mucous discharge from the nose appears, and respiratory distress, cyanosis and petechiae of the wattles and the comb occur Opisthotonos convulsions, ascending paresis and abnormal movements have also been observed. Death ensues, usually on the 6th to the 8th day, in

the United States the mortality rate is comparatively low in adult birds. The disease in fowl produces multiple focal necroses in the viscera and hemorrhages, especially in the respiratory and the alimentary tracts; at times an interstitial pneumonitis is observed. The CNS may show localized meningo-encephalitis characterized by areas of necrosis of the ground substance, neuronal necrosis and degeneration, and small hemorrhages.

The proved cases in man occurred in laboratory or poultry workers handling the virus, in whom the incubation period varied from a few hours to 2 days The disease manifests itself as a unilateral superficial conjunctivitis without involvement of the cornea; or a syndrome, consisting of conjunctivitis, preauricular lymphadenitis, headache, malaise and chills, without significant rise in temperature, may occur All reported patients have recovered completely within 1 or 2 weeks.

The natural disease is observed in chickens, turkeys, pheasants, guinea fowl, sparrows, crows, francolins and parrots; experimental infection has been achieved in chick embryos, ducks, geese, pigeons and several varieties of wild birds Intracerebral inoculation of the virus into mice, hamsters, cotton rats and rhesus monkeys causes a meningo-encephalitis which becomes increasingly severe with repeated passage and adaptation to these hosts (Wenner et al, 1950) Large doses of virus given to mice intranasally produce consolidation of the lungs, but it is not possible to transfer the disease from mouse to mouse in this manner Ferrets show no apparent malady after intranasal application of the active agent but develop specific antibody Guinea pigs, *rabbits and pigs are resistant. Transmission* of the disease can be effected by means of blood, brain, viscera, oral and nasal secretions, and feces All routes of inoculation, except the intramuscular which may be followed by irregular results, can be employed successfully. The diameter of ND virus as determined by filtration through gradocol membranes is 80 to 120 mμ; 115 mμ (Bang, 1946) by elecronmicrography

The virus particle exists in spherical and filamentous forms which like influenza virus,
rimentally
The aver-
0 mμ and

that of the filaments 90 mμ. The length of the latter form varies between 270 and 980 mμ (Kilham et al., 1951). It is said to be filterable through Berkefeld V, N and W candles, Chamberland L_3 and L_5 filters and Seitz pads It is inactivated at 60° C for 30 minutes and at 55° C. for 45 minutes by photodynamic action of methylene blue, by ultraviolet radiation, by 1:5,000 dilution of formalin, and by N/50 sodium hydroxide in 1 hour but not by N/25 hydrochloric acid Newcastle virus remains active at pH 4 for at least a week (Brandly et al, 1946). The virus is preserved in 50 per cent glycerol, by being kept frozen at −70° C., and by lyophilization.

Newcastle disease virus multiplies readily in embryonated eggs and in cultures of chick *embryonic tissues or HeLa cells (Tyrrell,* 1955). Cellular destruction is produced in such tissue cultures. Allantoic fluid from infected embryos will fix complement with immune serum, will hemolyse chicken erythrocytes and is capable of causing hemagglutination of fowl erythrocytes and those of certain other species (Burnet, 1943). By centrifugation it is possible to separate a large (L) and a small (S) hemagglutinating component which have differing elution properties (Granoff and Henle, 1954). Hemolytic activity appears to be associated with the L component only ND virus hemagglutination is inhibited by serum antibody, and this has made possible in vitro technics for measuring the concentrations of viruses or antibody. Human erythrocytes sensitized with ND virus are agglutinated by specific antisera and by the sera of some patients with infectious mononucleosis (Burnet and Anderson, 1946, Florman, *1949, Evans, 1955) An antigenic relationship* to mumps was suggested by the observation by Jungherr et al. (1949) that mumps convalescents may develop neutralizing antibody to Newcastle disease virus However, as these studies were performed with unheated sera, which might have contained nonspecific inhibitors (see below), and since

susceptible lower animals. They are produced

also by animals which are resistant to infection following parenteral injection of the virus Specific antibodies can be detected, and their titer can be determined by means of the hemagglutination-inhibition test, the virus-neutralization test in chick embryos, or the complement-fixation test

The diagnosis of Newcastle disease in human beings is made by: (1) a history of exposure to the virus or to fowl ill with the disease, (2) isolation of the virus from the conjunctival exudate and its identification by means of the hemagglutination-inhibition test, and (3) determination of the development of specific neutralizing antibody by tests on paired sera collected from patients during the acute and the convalescent stages of the disease Because of the presence in human serum of a heat-labile nonspecific neutralizing factor it is essential that suspect sera be inactivated at 56° C for 30 minutes before being used in neutralization tests (Ginsberg and Horsfall, 1949, Howitt, 1950). No specific treatment is available Antibiotics have no effect on the virus

The few human cases reported point to the fact that exposure to the virus or to affected fowl is essential for infection In fowl the disease is ordinarily conveyed by contact A natural resistance develops with age, and passive immunity can be conferred upon a chick by way of the egg yolk of an immune dam, Brandly et al, 1946a The prevention of the disease in man depends on protection from infection when exposed to the virus or the affected fowl The prevention of the disease in birds has been shown to be possible through the use of formolized or irradiated vaccines, or, if a stronger and more durable immunity is desired, by the employment of such vaccines, followed by a vaccine consisting of modified, active virus, Brandly et al, 1946c

EQUINE INFECTIOUS ANEMIA

(SYNONYMS. Swamp fever of horses, pernicious anemia of horses, equine "malaria")

Equine infectious anemia is a viral disease of horses, mules and donkeys which is widely distributed over the world In equines it appears in an acute form enduring for 4 days to 3 weeks, a chronic type which may last for years accompanied by viremia or as a subacute, quiescent illness The mortality varies between 30 and 70 per cent The question of human susceptibility remains open since it has been reported as transmissible to man (Peters, 1945, Kral, 1949) while Stein et al (1944) and Dreguss and Lombard (1954) present considerable evidence against human infection The reported disease in man manifested itself by fever, anemia, diarrhea, renal pain and a "viremia" The blood of one person was reported as infective for horses over a period of 3 years

The virus was discovered by Vallée and Carré, 1904, its diameter as determined by filtration through gradocol membranes is 18 to 50 mμ, it is inactivated by heating to 60° C. for 1 hour. Equine animals are susceptible, while ordinary laboratory animals are resistant The observation by Reagan et al (1948) that rabbits develop a transmissible febrile illness following inoculation of infected horse blood awaits confirmation Transmission in equines can be effected by the parenteral injection of infectious material, by biting flies (*Stomoxys calcitrans*), or by virus coming in contact with abraded skin or mucous membranes (Stein et al, 1944). The idea, formerly held, that infection by ordinary contact or feeding is possible, has not been substantiated experimentally However, it has been demonstrated that infected mares may have virus in their milk and that suckling foals, although inapparently harboring the disease, may still be susceptible to experimental infection by a peripheral route There is no specific treatment, and control measures consist of isolation or extermination of affected animals. It is important to note that all antisera made in equine animals for use in man or equine animals must be produced in a manner to eliminate the possibility of their containing the virus of infectious anemia in an active state. The monograph of Dreguss and Lombard (1954) contains an extensive description of this disease and its bibliography.

CAT-SCRATCH DISEASE

(SYNONYMS. Cat-scratch fever, benign lymphoreticulosis)

Cat-scratch disease is a systemic illness, rarely fatal, characterized by malaise, fever, and a lymphadenitis which may resemble neo-

the United States the mortality rate is comparatively low in adult birds. The disease in fowl produces multiple focal necroses in the viscera and hemorrhages, especially in the respiratory and the alimentary tracts; at times an interstitial pneumonitis is observed. The CNS may show localized meningo-encephalitis characterized by areas of necrosis of the ground substance, neuronal necrosis and degeneration, and small hemorrhages

The proved cases in man occurred in laboratory or poultry workers handling the virus, in whom the incubation period varied from a few hours to 2 days. The disease manifests itself as a unilateral superficial conjunctivitis without involvement of the cornea, or a syndrome, consisting of conjunctivitis, preauricular lymphadenitis, headache, malaise and chills, without significant rise in temperature, may occur All reported patients have recovered completely within 1 or 2 weeks

The natural disease is observed in chickens, turkeys, pheasants, guinea fowl, sparrows, crows, francolins and parrots; experimental infection has been achieved in chick embryos, ducks, geese, pigeons and several varieties of wild birds Intracerebral inoculation of the virus into mice, hamsters, cotton rats and rhesus monkeys causes a meningo-encephalitis which becomes increasingly severe with repeated passage and adaptation to these hosts (Wenner et al, 1950). Large doses of virus given to mice intranasally produce consolidation of the lungs, but it is not possible to transfer the disease from mouse to mouse in

rabbits and pigs are resistant. Transmission of the disease can be effected by means of blood, brain, viscera, oral and nasal secretions, and feces All routes of inoculation, except the intramuscular which may be followed by irregular results, can be employed successfully. The diameter of ND virus as determined by filtration through gradocol membranes is 80 to 120 mμ; 115 mμ (Bang, 1946) by electronmicrography.

The virus particle exists in spherical and filamentous forms which, like influenza virus, develop from the surface of experimentally infected chick chorio-allantois cells The average diameter of the spheres is 100 mμ and that of the filaments 90 mμ. The length of the latter form varies between 270 and 980 mμ (Kilham et al., 1951). It is said to be filterable through Berkefeld V, N and W candles, Chamberland L_3 and L_5 filters and Seitz pads It is inactivated at 60° C. for 30 minutes and at 55° C. for 45 minutes by photodynamic action of methylene blue, by ultraviolet radiation, by 1:5,000 dilution of formalin, and by N/50 sodium hydroxide in 1 hour but not by N/25 hydrochloric acid. Newcastle virus remains active at pH 4 for at least a week (Brandly et al, 1946). The virus is preserved in 50 per cent glycerol, by being kept frozen at −70° C., and by lyophilization.

Newcastle disease virus multiplies readily in embryonated eggs and in cultures of chick embryonic tissues or HeLa cells (Tyrrell, 1955). Cellular destruction is produced in such tissue cultures. Allantoic fluid from infected embryos will fix complement with immune serum, will hemolyse chicken erythrocytes and is capable of causing hemagglutination of fowl erythrocytes and those of certain other species (Burnet, 1943). By centrifugation it is possible to separate a large (L) and a small (S) hemagglutinating component which have differing elution properties (Granoff and Henle, 1954). Hemolytic activity appears to be associated with the L component only. ND virus hemagglutination is inhibited by serum antibody, and this has made possible in vitro technics for measuring the concentrations of viruses or antibody. Human erythrocytes sensitized with ND virus are agglutinated by specific antisera and by the sera of some patients with infectious mononucleosis (Burnet and Anderson, 1946; Florman, 1949, Evans, 1955). An antigenic relationship to mumps was suggested by the observation by Jungherr et al. (1949) that mumps convalescents may develop neutralizing antibody to Newcastle disease virus However, as these studies were performed with unheated sera, which might have contained nonspecific inhibitors (see below), and since

lowing infection with the agent in man and susceptible lower animals. They are produced

pecially the mouse, in which the CNS and particularly the meninges and the choroid plexuses are involved, it is transmissible to man in whom the infection produces a marked diversity of signs and symptoms

History

The virus of lymphocytic choriomeningitis (LCM) was isolated from a monkey by Armstrong and Lillie in 1934 during the course of an investigation of St Louis encephalitis Shortly thereafter this agent was found in the cerebrospinal fluid of several human patients in whom a clinical diagnosis of benign aseptic meningitis had been made (Rivers and Scott, 1935) Lepine et al (1937) demonstrated that by subcutaneous injection of the virus from mice, performed as a therapeutic measure, LCM could be induced in human beings and that the disease was transmissible in man by means of intramuscular inoculations of infected blood Natural and laboratory infections are not uncommon, and these are discussed in the general review by Janeway and Farmer (1942) The intensive investigations of Traub (1936) focused attention on rodents, particularly mice, as both a vector and a reservoir of the virus of LCM

Clinical Picture

Wallgren (1925) used the term "acute aseptic meningitis" to designate a clinical syndrome in man that he thought was a nosologic entity. He described it as an acute febrile, nonfatal malady characterized by symptoms and signs of meningeal irritation and associated at times with infection of the upper respiratory tract Now it is known that acute aseptic meningitis is not a nosologic entity but represents a clinical syndrome which may be caused by more than one etiologic agent, one of which is the virus of lymphocytic choriomeningitis

Infection by this virus may assume a number of different clinical forms (Smadel et al, 1942, Adair et al, 1953) such as aseptic meningitis, grippe, meningo-encephalomyelitis and acute fatal systemic disease, often it is clinically inapparent. In most instances the meningeal and grippelike types prevail After an unknown period of incubation, the onset is sudden, frequently with symptoms and signs similar to those of influenza In many patients, this is all that happens, and recovery ensues promptly In others, the grippe phase is followed by definite signs of meningitis which may endure for about 2 weeks, complete recovery is the rule During the febrile period, virus is found in the blood, the cerebrospinal fluid, the urine and the nasopharyngeal secretions In the other neurologic or systemic forms, which are seen only occasionally, the disease takes on the syndrome referable to the extent and the location of lesions in the CNS or other organs, these forms are sometimes fatal Paralytic manifestations are rare The virus can be recovered from the CNS or from the lungs of patients dying of the disease There are many instances in which neutralizing antibody is found in the blood of a person who gives no history of an attack of the ailment, these are examples of clinically inapparent infection

In the experimental disease in man (Lépine et al, 1937) the incubation period was from 36 to 72 hours, which was followed by 2 or 3 febrile waves enduring over a 3-week period, the last febrile reaction was accompanied in about 50 per cent of the subjects by headache, vomiting and positive Kernig sign that lasted for 2 or 3 days

During the acute phase the blood count reveals a mild polymorphonuclear leukocytosis The cerebrospinal fluid is under increased pressure, protein is slightly increased, but the amount of sugar may be normal or abnormally low, pleocytosis occurs with usual counts of 150 to 400 lymphocytes per cu mm and sometimes as many as 1700 to 33 000 per cu mm have been reported

Pathologic Picture

The occasional fatal case of the encephalitic or myelitic type showed inflammatory changes in the meninges, the ependyma and the choroid plexuses characterized by marked infiltration with lymphocytes Otherwise, the lesions corresponded to those observed generally in the viral encephalitides In rare fatal cases of the acute systemic type of the disease, the lungs and the liver showed inflammatory reactions (Smadel et al, 1942)

Experimental Infection, Host Range

The virus is transmissible to man, albino mice, guinea pigs, monkeys, dogs, rats, gray mice, chimpanzees and chick embryos. Rabbits, pigs and birds are apparently insusceptible The laboratory animals of choice for in-

plastic disease *Its etiology remains obscure,* although certain workers (Mollaret et al, 1956) consider its causal agent to be a virus related to the psittacosis-lymphogranuloma group The syndrome was first described under the name *la maladie des griffes de chat,* Debré et al., 1950, but since only a portion of the cases have a history of contact with cats, the term "benign lymphoreticulosis," proposed by Mollaret et al, 1950, may have some justification. The disease is not uncommon

Most patients have a history of a cat-bite, a cat-scratch or merely having been licked by a cat a few days prior to illness Contact with cat excreta has resulted in a familial outbreak of the disease A cutaneous lesion resembling a small pustular furuncle appears in about 50 per cent of cases and may represent the primary pathologic reaction Following an incubation period of 2 to 6 weeks the regional lymph nodes draining the area become inflamed, swollen, painful and may suppurate, mild generalized lymphadenopathy and splenomegaly are also present. Malaise, chills and fever are common, and a macular rash over the extremities is not unusual (Greer and Keefer, 1951, Daniels and MacMurray, 1952)

In the majority of cases the illness is mild and of short duration, but suppurative lymph nodes may persist for months and require surgical drainage or removal Other variant chronic forms include a conjunctivitis resembling Parinaud's oculoglandular syndrome (Debré and Job, 1954) and meningo-encephalitis (Stevens, 1952) Included in a differential diagnosis are Hodgkins disease, lymphogranuloma venereum, tularemia, acute and chronic bacterial adenitis and other diseases involving the lymphatic system Fatal cases are rare (Debré and Job, 1954)

Successful serial passage of the agent in lymph-node suspensions to the monkey, *Aethiops sabaeus,* has been reported by Mollaret et al. (1951, 1956), but macacus monkeys and baboons were resistant. These findings were not confirmable by Debré and Job (1954), who were also unable to infect mice, guinea pigs, rabbits, ferrets, dogs, cats, embryonated eggs or tissue cultures of human [illegible] matory reticular and endothelial hyperplasia and early sclerosis at the periphery of the granuloma Germinal follicles contain small abscesses which coalesce to form larger areas of necrosis Spontaneous or surgical drainage is followed by rapid healing Diagnosis is facilitated by an intradermal and generalized febrile reaction resembling the Frei test to heat-inactivated suspensions of infected lymph nodes or pus, Mollaret et al, 1950 (Greer and Keefer, 1951). The technic of preparing the antigen is outlined by Debré and Job (1954).

The etiology of this infectious disease remains unsettled Cats harboring the virus remain well, and since they have negative intradermal reactions may perhaps be only passive carriers. Evidence that the agent of cat-scratch disease belongs to the psittacosis-lymphogranuloma group of viruses has been presented in a series of reports by Mollaret et al (1956) Inoculation of cercopithecus monkeys with infectious human material produced a granulomatous lymphadenitis which could be transmitted serially Stained sections of human and monkey nodes contain large members of intracellular and extracellular granules resembling the elementary bodies of psittacosis Although the Frei test is usually negative, sera of persons convalescent from cat-scratch disease will often fix complement in the presence of the psittacosis-lymphogranuloma group antigen On the other hand, the failure of cat-scratch material to infect embryonated eggs (Debré and Job, 1954) leaves unsettled the relationship of this virus to other agents What, if any, connection exists between the viruses of cat-scratch disease and feline pneumonitis (Baker, 1944) also remains to be determined

Because most patients recover spontaneously, the effect of treatment is difficult to appraise Chlortetracycline and other broad-spectrum antibiotics are reported to accelerate recovery

LYMPHOCYTIC CHORIOMENINGITIS

(Synonyms: LCM; choriomeningitis, *maladie d'Armstrong*)

Introduction

Lymphocytic choriomeningitis is an endemic viral infection of lower animals, es-

pecially the mouse, in which the CNS and particularly the meninges and the choroid plexuses are involved, it is transmissible to man in whom the infection produces a marked diversity of signs and symptoms

History

The virus of lymphocytic choriomeningitis (LCM) was isolated from a monkey by Armstrong and Lillie in 1934 during the course of an investigation of St Louis encephalitis Shortly thereafter this agent was found in the cerebrospinal fluid of several human patients in whom a clinical diagnosis of benign aseptic meningitis had been made (Rivers and Scott, 1935). Lepine et al (1937) demonstrated that by subcutaneous injection of the virus from mice, performed as a therapeutic measure, LCM could be induced in human beings and that the disease was transmissible in man by means of intramuscular inoculations of infected blood Natural and laboratory infections are not uncommon, and these are discussed in the general review by Janeway and Farmer (1942) The intensive investigations of Traub (1936) focused attention on rodents, particularly mice, as both a vector and a reservoir of the virus of LCM

Clinical Picture

Wallgren (1925) used the term "acute aseptic meningitis" to designate a clinical syndrome in man that he thought was a nosologic entity He described it as an acute febrile, nonfatal malady characterized by symptoms and signs of meningeal irritation and associated at times with infection of the upper respiratory tract Now it is known that acute aseptic meningitis is not a nosologic entity but represents a clinical syndrome which may be caused by more than one etiologic agent, one of which is the virus of lymphocytic choriomeningitis

Infection by this virus may assume a number of different clinical forms (Smadel et al, 1942, Adair et al, 1953) such as aseptic meningitis, grippe, meningo encephalomyelitis and acute fatal systemic disease, often it is clinically inapparent In most instances the meningeal and grippelike types prevail After an unknown period of incubation, the onset is sudden, frequently with symptoms and signs similar to those of influenza In many patients, this is all that happens, and recovery ensues promptly In others, the grippe phase is followed by definite signs of meningitis which may endure for about 2 weeks, complete recovery is the rule During the febrile period, virus is found in the blood, the cerebrospinal fluid, the urine and the nasopharyngeal secretions. In the other neurologic or systemic forms, which are seen only occasionally, the disease takes on the syndrome referable to the extent and the location of lesions in the CNS or other organs, these forms are sometimes fatal Paralytic manifestations are rare The virus can be recovered from the CNS or from the lungs of patients dying of the disease There are many instances in which neutralizing antibody is found in the blood of a person who gives no history of an attack of the ailment; these are examples of clinically inapparent infection.

In the experimental disease in man (Lépine et al, 1937) the incubation period was from 36 to 72 hours, which was followed by 2 or 3 febrile waves enduring over a 3-week period, the last febrile reaction was accompanied in about 50 per cent of the subjects by headache vomiting and positive Kernig sign that lasted for 2 or 3 days

During the acute phase the blood count reveals a mild polymorphonuclear leukocytosis The cerebrospinal fluid is under increased pressure, protein is slightly increased, but the amount of sugar may be normal or abnormally low, pleocytosis occurs with usual counts of 150 to 400 lymphocytes per cu mm and sometimes as many as 1700 to 33,000 per cu mm have been reported

Pathologic Picture

The occasional fatal case of the encephalitic or myelitic type showed inflammatory changes in the meninges, the ependyma and the choroid plexuses characterized by marked infiltration with lymphocytes Otherwise, the lesions corresponded to those observed generally in the viral encephalitides In rare fatal cases of the acute systemic type of the disease, the lungs and the liver showed inflammatory reactions (Smadel et al, 1942)

Experimental Infection, Host Range

The virus is transmissible to man, albino mice, guinea pigs, monkeys, dogs, rats, gray mice, chimpanzees and chick embryos Rabbits, pigs and birds are apparently insusceptible The laboratory animals of choice for in-

oculation of the virus are the guinea pig and the albino mouse. Mice are best infected by intracerebral and intranasal routes, infection being obtained by these routes with 10^{-7} and 10^{-3} dilutions of virus, respectively. Mice, 5 to 12 days after inoculation, develop tremors and convulsions which characteristically terminate in a few seconds in generalized rigidity; death occurs in 1 to 3 days after onset of illness. If small doses of the virus are inoculated peripherally, a nonfatal infection may be induced which immunizes the animals; large doses may cause fatal infection after intraperitoneal administration. Guinea pigs, like mice, are best infected by the intracerebral route; after subcutaneous or intraperitoneal inoculation, death may occur within 9 to 16 days. The virus can be found in the brain, blood, spleen, lungs and urine of mice and guinea pigs and, according to Shwartzman (1944), is firmly associated with their erythrocytes

The pathologic picture is one of a meningoplexal and perivascular infiltration by

in the kidney, the salivary gland and the pancreas. In mice, also, there is often serous pleurisy, serous peritonitis and hepatitis; and necrosis, hemorrhage and serofibrinous exudate are observed in the lymphatic organs. Hepatitis is seen also in infected guinea pigs and monkeys. Thus, in experimental infection, the virus is generalized through the CNS and the viscera and is associated with inflammatory lesions which persist for a long time during convalescence (Lillie, 1950). Different strains of the virus vary greatly in their pathogenicity for and behavior in experimental animals.

The virus occurs naturally in several species of animals, mice, guinea pigs, monkeys and dogs have been found to harbor it. Traub (1935) found that the spontaneous disease in mice is transmitted by mothers to their young in utero or shortly after birth and that the virus is propagated or maintained in a colony by normal-appearing carriers.

Etiology

The diameter of the virus is from 40 to 60 mμ as determined by filtration through gradocol membranes, and from 37 to 55 mμ as estimated from results of ultracentrifugation. It passes through Berkefeld V, N and W candles and Seitz filters. It is preserved in 50 per cent buffered glycerol, by being kept in the frozen state at $-70°$ C, and by lyophilization; in a brain suspension it is not stable at room temperature. It can be cultivated in vitro in minced mouse- or chick-embryo tissue suspended in a mixture of salt solution and serum, on the chorio-allantois, or in the yolk sac of 11- or 12-day-old chick embryos. The membranes and the brains yield virus with a titer of up to 10^{-7} by intracerebral titration in mice. However, infected embryos hatch, and the chicks survive. Smadel and Wall (1941) have demonstrated the presence of a specific soluble substance separable from the active virus in the organs, chiefly spleens, of infected guinea pigs and mice.

Complement-fixing and neutralizing antibodies appear in the serum of convalescent human beings; the former is first noted from about 1 to 3 weeks after onset of illness, the latter not until 6 to 10 weeks. Neutralizing antibody is known to persist for at least 3 years in persons who have had the disease, while the amount of complement-fixing antibody begins to decline 3 to 6 weeks after the onset of an attack Both kinds of antibody are also produced in experimental animals after infection with active virus or after immunization with inactive virus, both appear within 10 days; how long they endure is not known.

Diagnosis

Since the clinical course of lymphocytic choriomeningitis cannot be differentiated from that which follows infection with a number of other neurotropic viruses, including poliomyelitis, ECHO virus infection, mumps, herpes, etc, definitive diagnosis rests upon isolation and identification of the agent and serologic tests. The virus may be obtained from the blood, the cerebrospinal fluid or CNS tissues. The mouse and the guinea pig are the species of choice for isolation studies, but one should be certain that the stock of animals used for diagnostic purposes is free of virus Neutralization and complement-fixation tests are performed with acute and convalescent

sera Detailed diagnostic procedures can be found in Adair et al (1953) and in Hammon (1956).

Treatment

There is no specific treatment. Antifolic acid compounds were capable of prolonging or sparing the lives of experimentally infected mice, although their prolonged viremia was unaffected (Haas and Stewart, 1956)

Epidemiology

The disease occurs in persons of all ages, with 20 to 30 years the most frequent and males and females being equally affected Most cases occur in winter and spring Its incidence in the United States is difficult to estimate Adair et al. (1953) found LCM to be the cause in approximately 9 per cent of 854 sporadic cases of aseptic meningitis However, neutralizing antibody was present in 11 per cent of 2000 sera collected at random from persons without a history of clinical LCM (Armstrong, 1941). Moreover, the disease assumes an important role in public health because its virus is present in high titer in certain lower animals, such as the gray or house mouse (*Mus musculus*) The virus may persist in carrier mice throughout their lives and exist as an epizootic infection in a colony (Traub, 1936). Rowe (1954) has demonstrated that acquired immunity in the albino mouse is associated with persistence of the virus The virus escapes from the mouse by way of the nasal secretions, the urine, the feces and the semen, thus possibly contaminating the habitat of man It has been suggested by Armstrong (1941) that dust may be a source of human infection

The virus most likely enters man by the upper respiratory tract, laboratory infections are not uncommon Shaughnessy and Milzer (1939) have suggested that arthropods, such as culicine mosquitoes, stable flies, wood ticks and baby lice, may serve as vectors for transmitting the disease from infected to normal rodents and to man Still another possible means of conveying infection from mouse to mouse, and mouse to man has been suggested by Syverton et al (1947), namely, through superinfected *Trichinella spiralis* or its larvae

Control Measures

The eradication of rodent or other animal carriers, together with the maintenance of high standards of sanitation, would appear to be important measures for control of the disease in a population. A patient's excretions should be disinfected, since they may contain the virus

ENCEPHALOMYOCARDITIS

(Synonyms: Columbia-SK, MM, Mengo, F viruses, etc. See Table 41)

Introduction

Members of this group of viruses were discovered in widely separated areas and in certain instances were regarded as different agents. However, they are now generally recognized as strains of a single virus which are immunologically indistinguishable All are highly infectious for several rodents, which probably serve as reservoirs. Encephalomyocarditis infection in man clinically resembles other neurotropic viral diseases

History

The first of these strains to be recognized was isolated by Jungeblut and Sanders, 1940, from cotton rats which were being used for the passage of the Yale-SK strain of polio-

....

from hamster brain inoculated with material from human spinal cord and medulla taken from a patient who had died of clinically diagnosed paralytic disease, Jungeblut and Dalldorf, 1943 Because both agents were discovered under circumstances where material, either known to be or suspected of being infected with poliomyelitis virus, was being passaged through rodents, considerable confusion surrounded the relationship of the agents to poliomyelitis virus. Indeed, for a time it was thought that they represented murine variants of the latter. Subsequent study has failed to provide adequate evidence of any antigenic relationship between the agents of this group and poliomyelitis

The encephalomyocarditis (EMC) and Mengo encephalomyelitis strains were isolated from captive monkeys in Florida, Helwig and Schmidt, 1945, and in Uganda, Dick et al, 1948, respectively. Strains of Mengo virus were also obtained from mosquitoes (*Taeniorhynchus fuscopennatus*) and a wild mongoose caught in the vicinity of a monkey compound at Entebbe, Uganda

Subsequent isolations of EMC virus have

been made in the southeastern United States from both primates and rodents These are summarized in Table 41

Human infections with encephalomyocarditis have been associated with a variety of clinical signs varying from a mild febrile illness to a severe encephalomyelitis. In several instances close proximity to rodents has been noted. Beller and Keller (1949) isolated a strain in 1943 from the cerebrospinal fluid of a child with Guillain-Barre type of polyradiculitis The Mengo strain was isolated from a laboratory worker who developed a severe meningo-encephalitis while engaged in studies on this virus, Dick et al, 1948 Additional isolates have been reported from adults and children with nonfatal illnesses diagnosed as paralytic poliomyelitis, aseptic meningitis and encephalomyelitis (See Table 41.) There is some evidence that EMC infection may appear in localized outbreaks (Bieling and Koch, 1952). A mild febrile disease, called "3-day fever," appeared in epidemic form among U. S. troops quartered in Manila in *1945-46* *Neutralizing antibodies* to EMC were demonstrated in the sera taken from many of these patients during convalescence (Smadel and Warren, 1947)

CLINICAL PICTURE

The clinical features are varied in those few cases in which the evidence that they were

caused by EMC virus is acceptable A febrile CNS disease with a lymphocytic pleocytosis sometimes accompanied by one or more signs of paralysis was the most common finding in 14 well-studied cases (Gajdusek, 1955) Myocarditis has not been one of the symptoms of EMC infections in humans

The single known human infection with the Mengo strain was characterized by an elevated temperature lasting 4 days accompanied by severe headache, nuchal rigidity, photophobia, vomiting and short episodes of delirium, Dick et al, 1948 The patient recovered rapidly, the only sequelae being a transient unilateral nerve deafness Mengo virus was isolated from the blood on the 1st and the 2nd days of illness by animal inoculation, and neutralizing antibodies were demonstrated in the patient's serum following recovery.

In the cases occurring in the Philippines, onset of the disease was sudden, with severe headache and a moderately high fever, reaching 104° F in some instances The fever lasted for 2 or 3 days and was often accompanied by pharyngitis, stiff neck, positive Kernig's sign and hyperactive deep reflexes An occasional patient was comatose on admission to the hospital The only notable laboratory finding was pleocytosis of from 50 to 500 cells, principally lymphocytes in the spinal fluid All patients recovered promptly and usually were discharged from the hospital in 4 or 5 days There were no known sequelae, and no signs of cardiac disease were observed On the basis of these findings, a clinical differentiation of encephalomyocarditis from aseptic meningitis, nonparalytic poliomyelitis and the denguelike fevers was not possible

Pathologic Picture

Nothing is known of the pathologic picture in human beings, because no deaths have been reported among the patients with proved virus infection

Experimental Infection, Host Range

Although all strains of the encephalomyocarditis group can multiply in most laboratory animals, the response varies with the host Mice and hamsters of all ages die following inoculation by any of the usual routes with a $10^{-7.0}$ dilution of a suspension of brain tissue from moribund mice, hamsters or cotton rats Within 72 or 96 hours, such an inoculation produces signs consisting of ruffled fur, lethargy and flaccid paralysis, which are invariably followed by prostration and death When greater concentrations of virus are given intracerebrally, death occurs as early as 18 hours after inoculation; animals receiving this amount of virus show no paralysis but die with signs of an acute encephalitis Occasionally, mice can be infected with virus-contaminated drinking water Guinea pigs and rabbits experience an infection characterized by fever for the first 4 or 5 days after inoculation Paralysis, occasionally fatal, occurs in 10 to 50 per cent of infected guinea pigs, all animals develop infection as evidenced by the appearance of neutralizing antibody The disease is not fatal in rabbits The resistance of the albino rat increases with age (Kilham et al, 1955) and the adult rat undergoes only an inapparent infection following a massive inoculation, although considerable virus may persist in the central nervous system for several weeks The response of rhesus monkeys to viruses of the EMC group is variable, ranging from an acute febrile course followed by death within the first week to a mild infection characterized by a short fever and subsequent appearance of serum antibodies Paralysis in monkeys is not infrequent, but the animals usually recover The viruses can be propagated in chick embryos, causing death in 72 to 96 hours without pathognomonic lesions Viremia occurs during some portion of the febrile period in infected animals of all species mentioned above Virus usually persists for several days, and blood specimens when titered in mice are infectious in dilutions of $10^{-3.0}$ to $10^{-4.0}$ Viruses of the EMC group can be cultivated in Ehrlich ascites cells, the L strain of mouse fibroblasts, the HeLa and the KB Lines of human malignant cells Strains differ in their cytopathogenicity with the EMC and the Mengo strains being of greater pathogenicity (Jungeblut, 1958)

Lesions in experimentally infected animals are found in the entire central nervous system and in striated and cardiac muscles This is a common feature of the agents of the

Pathologic Picture

Nothing is known of the pathologic picture in human beings, because no deaths have been reported among the patients with proved virus infection

Experimental Infection, Host Range

Although all strains of the encephalomyocarditis group can multiply in most laboratory animals, the response varies with the host Mice and hamsters of all ages die following inoculation by any of the usual routes with a $10^{-7.0}$ dilution of a suspension of brain tissue from moribund mice, hamsters or cotton rats Within 72 or 96 hours, such an inoculation produces signs consisting of ruffled fur, lethargy and flaccid paralysis, which are invariably followed by prostration and death When greater concentrations of virus are given intracerebrally, death occurs as early as 18 hours after inoculation; animals receiving this amount of virus show no paralysis but die with signs of an acute encephalitis Occasionally, mice can be infected with virus-contaminated drinking water Guinea pigs and rabbits experience an infection characterized by fever for the first 4 or 5 days after inoculation Paralysis, occasionally fatal, occurs in 10 to 50 per cent of infected guinea pigs; all animals develop infection as evidenced by the appearance of neutralizing antibody The disease is not fatal in rabbits The resistance of the albino rat increases with age (Kilham et al, 1955) and the adult rat undergoes only an inapparent infection following a massive inoculation, although considerable virus may persist in the central nervous system for several weeks The response of rhesus monkeys to viruses of the EMC group is variable, ranging from an acute febrile course followed by death within the first week to a mild infection characterized by a short fever and subsequent appearance of serum antibodies Paralysis in monkeys is not infrequent, but the animals usually recover The viruses can be propagated in chick embryos, causing death in 72 to 96 hours without pathognomonic lesions Viremia occurs during some portion of the febrile period in infected animals of all species mentioned above Virus usually persists for several days, and blood specimens when titered in mice are infectious in dilutions of $10^{-3.0}$ to $10^{-4.0}$ Viruses of the EMC group can be cultivated in Ehrlich ascites cells, the L strain of mouse fibroblasts, the HeLa and the KB Lines of human malignant cells Strains differ in their cytopathogenicity with the EMC and the Mengo strains being of greater pathogenicity (Jungeblut, 1958)

Lesions in experimentally infected animals are found in the entire central nervous system and in striated and cardiac muscles This is a common feature of the agents of the

EMC group, hence their generally accepted designation The extent of the pathologic changes is related to the portal of inoculation and duration of disease. If the virus is inoculated directly into a muscle, e.g., the gastrocnemius, there is a rapidly progressing necrosis of the muscle fibers accompanied by edema and inflammatory reaction. Cardiac lesions require longer to develop, and, in animals dying after a number of days, these appear grossly as pale yellow plaques 0.5 to 2.0 [illegible]
tent [illegible]
a si [illegible]
myocarditis affecting a large area of the heart. The pathologic process appears to begin with a mild perivascular monocytic infiltration and with swelling and loss of striations of muscle fibers which progress to complete necrosis. Cellular infiltrations are usually extensive, lymphocytes and histiocytes predominating (Schmidt, 1948) Focal granulomatous lesions containing multinucleated giant cells have also been observed occasionally in the hearts of monkeys and mice. The viruses of the EMC group are also highly neurotropic with the severity of lesions varying with the duration of the disease Thus, in animals which survive only 1 or 2 days lesions in the CNS are minimal. When, however, the incubation period is prolonged to 4 or 5 days by giving a small dose of virus by a peripheral route, the usual lesions of encephalitis are encountered, which consist of congestion of the capillaries and infiltration of lymphocytes and mononuclear cells into the subarachnoid space, perivascular spaces and cerebral parenchyma However, neither the meningitis nor the cuffing is intense. The most striking and characteristic change consists of sharply demarcated focal areas of necrosis scattered throughout the central nervous system, most common in the cerebellum where they usually involve the granular and Purkinje cells layers.

Etiology

The Columbia-SK, MM, EMC and Mengo encephalomyelitis agents are small viruses, readily passing through Berkefeld and Seitz filters and through gradocol membranes with average pore-diameters of 30 mμ; thus, according to results with gradocol membranes, they have diameters of 8 to 15 mμ. However, direct visualization by electronmicroscopy or determination of the sedimentation constants of highly purified preparations indicates a particle size of 25 to 29 mμ (Col.-SK, Jungeblut and Bourdillion, 1943; EMC, Weil et al., 1951). They are quite stable when stored at −70° C. and can also be preserved in 50 per cent glycerol or 0.05 molar glycine. They are inactivated by a temperature of 60° C. for 30 minutes and usually lose their infectivity following lyophilization Specific antibodies which cross-react equally with all strains appear in the sera of convalescent animals and man. In the rhesus monkey and in man antibodies may be present late in the first week or early in the second. Tests for neutralizing antibodies are performed in mice by means of intracerebral or intraperitoneal inoculation of serum-virus mixtures Complement-fixing antibodies have been found in the sera of immune hamsters, guinea pigs and rats (Warren et al., 1949b). Ability of members of the EMC group to agglutinate sheep erythrocytes was first reported by Hallauer (1949, 1951) and later by Olitsky and Yager (1949) and Gard and Heller (1951) Agglutination occurs at 4° C., and virus is eluted from the cells above 20° C. Agglutination is inhibited by specific immune serum The Columbia-SK, MM, EMC and Mengo strains of virus are indistinguishable by cross-protection, neutralization, complement-fixation and hemagglutination-inhibition technics. Differences in pathogenicity between the strains do not provide adequate criteria for their differentiation, as variations in strain pathogenicity for a given host or route of inoculation are readily produced by repeated adaptive passes An achievement of fundamental importance was made by Colter et al. (1957), who were able to isolate an infective ribonucleic acid from Ehrlich ascites cells infected with the Mengo strain, the first such preparation from a virus infecting mammalian cells.

Diagnosis

The diagnosis of encephalomyocarditis in man rests on the isolation and the identification of the virus and the demonstration of the development during convalescence of specific antibodies. Because of the possibility that laboratory animals, especially rodents, may harbor the virus, multiple isolations are desirable for a definitive diagnosis. The important differential generic characteristics that

serve to distinguish these strains from other known viruses are:

1. Small size and the ability to hemagglutinate; a property also shared by the ECHO viruses

2. A broad host range including the embryonated egg.

3. High infectivity by peripheral routes in a wide variety of adult hosts and disease in these hosts.

The symptoms and signs of the disease in man are not sufficiently diagnostic to permit its differentiation from a number of febrile neurologic infections

Treatment

Treatment is symptomatic

Epidemiology

Primary isolation of strains of EMC virus have been reported from a variety of rodents, the rhesus monkey, the chimpanzee and the mandrill baboon (Kissling et al, 1956) In addition, several species of Taeniorrhynchus mosquitoes were found naturally infected in Uganda, Dick et al, 1948 (Horgan, 1951) There is considerable evidence that rodents, in particular certain species of wild rats, constitute a reservoir for EMC virus. The albino rat, after intracerebral inoculation of virus, undergoes an inapparent infection, and considerable virus persists for several weeks in the central nervous system and the [illegible]

[illegible]

sues, urine and feces (Kilham et al, 1956) Contact transmission within cotton rats and infection by feeding in the case of albino mice has been demonstrated Further evidence that rats in nature may harbor strains of EMC virus is the finding of neutralizing antibodies in a significant proportion of *Rattus norvegicus* and *R alexandrinus* collected in certain areas of the United States and Canada (Warren et al, 1949a) and *R kyjabius* and *R coucha* trapped in Uganda (Horgan, 1951). Tests for antibody in other small animals in the same areas have been uniformly negative

Surveys of the incidence of neutraliz[illegible]

[illegible] 1954, Kellel and Vivell, 1954). These have shown that, whereas less than 3 per cent of healthy individuals have EMC antibody, a higher percentage (12% to 16%) of sera from cases of CNS disease neutralize this virus

Control Measures

No control measures are known

WARTS: VERRUCAE

There are several types of wart which vary in appearance, location and preference of age (van Rooyen and Rhodes, 1940). Those usually recognized are common warts, digitate warts, juvenile (plane) warts, filiform warts, genital warts and laryngeal papillomata. Common warts usually occur as discrete, oval, gray, dry growths on the hands Juvenile warts are small, flat growths usually occurring in groups on the face Digitate warts are growths broken into folds and are found on the face and the scalp. Filiform warts are delicate threadlike growths on the eyelids and the neck. Genital warts are small, gray, rough nodules which appear in the coronal sulcus of the penis or on the labia and around the vaginal orifice During pregnancy they increase in size but become smaller after its termination In the female, because of the moisture around the genital regions, warts may become large and secondarily infected with bacteria Laryngeal papillomata are flat or pedunculated and occur singly or in groups, they may recur after removal

It has been definitely shown that an agent filterable through Berkefeld candles of all grades of porosity is responsible for warts. The virus survives a temperature of 50° C for 30 minutes Furthermore, most workers believe that a single etiologic agent is responsible for the different types of wart mentioned Examination of extracts of certain papillomata of the skin by means of the electronmicroscope have revealed virus-like particles which tended to aggregate in [illegible]

[illegible] Kingery, 1921) Laryngeal papillomata are the only warts that have been transmitted to lower animals, and this was accomplished by injecting the infectious material into the

vaginal mucosa of bitches. Warts of dogs and cattle are not transmissible to man The incubation period in the experimental disease has been as follows in reported experiments. 1, 6, 8 and 20 months, respectively

If warts are made to bleed, new lesions may occur in neighboring parts of the skin. They are spread by direct or indirect contact in barber shops, bathing pools, chiropodists' offices, hairdressing establishments and other places of similar character The epithelium is the only tissue involved by some warts and shows a hyperkeratosis and many mitotic figures In some warts the deeper tissues are involved and at times have an inflammatory reaction As a rule, no specific inclusions have been found Warts usually disappear spontaneously, and there is evidence that some immunity is present in a patient after recovery Many kinds of treatment have been devised for warts, but none is specific

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum has been known as a clinical entity since 1817 The incubation period as determined by inoculation of human volunteers has been stated by 3 groups of investigators to be 50, 14 to 25, and 35 days, respectively The disease is characterized by the formation of multiple discrete nodules, limited to the epidermal layer of the skin, with an average diameter of 2 mm. The lesions may appear on the face, the arms, the legs, the buttocks, the genitalia, or the scalp, rarely, in the mucous membranes of the mouth, never on the soles and the palms The nodules are usually pearly white and painless, and at the top of each there is often an opening through which a small, white core can be seen Some of the lesions may become secondarily infected with bacteria and break down The disease is chronic, and several months may be required for recovery.

Lesions involve circumscribed areas of the epidermis which become thickened by hyperplasia and hypertrophy of infected epithelial cells. In the germinal layer, hyperplasia is evidenced by an increase in mitotic figures. In cells above the germinal layer, definite pathologic changes in the nuclei and the cytoplasm become obvious As the surface of the epidermis is approached, these changes become more and more marked so that eventually each cell is many times larger than normal, and the cytoplasm is filled with a large, hyaline, acidophilic, granular mass known as the molluscum body, which pushes the nucleus to the edge of the cell. A fully developed lesion is usually loculated, and there is very little reaction in the corium unless a nodule is secondarily infected by bacteria

The disease is not a serious one but is of particular interest because of discussions concerning the architecture and the significance of the molluscum body which at one time was considered a protozoan parasite. According to Goodpasture and King, 1927, and Goodpasture and Woodruff, 1931, the molluscum body is surrounded by desiccated cytoplasmic protein which extends into the structure to form trabeculae The covering and the trabeculae can be digested away by trypsin, this procedure leaves a sticky, gelatinous mass, within which numerous elementary bodies, first described by Lipschutz, 1907, are embedded According to van Rooyen (1938, 1939), the molluscum body is not a mixture of cytoplasmic material and virus elementary bodies but constitutes a foreign entity in the cell resulting from the growth of an elementary body which passes through developmental stages finally to form a large structure surrounded by a membrane with an operculum at one pole and filled with elementary bodies He believes that this structure has certain resemblances to the sporangium of a fungus, for example, *Rhino-sporidium seeberi*, which causes polyps in the nasal mucous membranes. Thin sections of molluscum contagiosum lesions have been studied by means of the electronmicroscope and histochemical technics (Rake and Blank, 1950; Banfield et al, 1951) In the early infected cell, elementary bodies are scattered in a random fashion throughout the cytoplasm These later become aggregated and surrounded by a large network of spongy matrix In the larger inclusion bodies this matrix is divided into cavities in which are clustered numerous elementary bodies. Within the elementary bodies are still smaller particles, with diameters of 80 to 100 mμ, which may represent some simpler structural unit. Molluscum bodies have diameters ranging from 20 to 30 μ, Lipschutz, 1907, while an elementary body

is brick-shaped and has average diameters of 200×300 mμ (Strauss et al, 1949) The latter stains well by Morosow's method Elementary bodies are said by various workers (van Rooyen and Rhodes, 1940) to pass through Chamberland L_1 and Berkefeld V filters The virus retains its activity in 50 per cent glycerol for at least a month A soluble, heat labile complement-fixing antigen has been prepared from suspensions of molluscum nodules by Mitchell (1953) However, only a fraction of cases possess complement-fixing antibodies and this procedure is not of diagnostic value No serologic relationship was demonstrable between molluscum virus and vaccinia, or fowlpox viruses

Man is the only known host, attempts to infect monkeys, apes, sheep, fowl, rabbits, guinea pigs, mice and embryonated eggs have been unsuccessful Molluscum contagiosum has a world-wide distribution, is particularly prevalent in certain areas, for example, Edinburgh; it is seen most frequently in children, but persons of all ages may be attacked, it is transmitted by personal contact or by fomites There is no specific treatment Some workers have stated that x-rays lead to rapid healing of the lesions, others have noted that healing takes place following bacterial invasion

EPIDEMIC VIRAL GASTROENTERITIS

(SYNONYMS Acute infectious gastroenteritis winter vomiting disease, febrile nonbacterial gastroenteritis)

Dysfunction of the human alimentary tract characterized by diarrhea and mild systemic signs may be associated with infection by a number of bacterial and viral agents The latter include poliomyelitis, certain of the ECHO viruses, Coxsackie A and B viruses, infectious hepatitis and herpes virus With the possible exception of certain of the ECHO types (Chap 26) these viruses are infrequently found in uncomplicated forms of epidemic gastroenteritis On the other hand, several agents of comparative obscurity have been isolated from outbreaks of this illness, and these are described in this section

The epidemic viral gastroenteritides are a nonseasonal, widespread communicable family of diseases whose clinical and epidemiologic features as they occur in the United States and abroad have been well delineated (Cook and Marmion, 1947, Gordon et al, 1949, Reimann et al, 1945, Jordan et al, 1953) Although its frequent appearance in public institutions and small communities has stimulated the majority of reports, cases may occur sporadically or in small endemic foci It affects infants as well as adults of all ages with some or all of the following symptoms anorexia, vomiting, gastric pain, fever, dizziness, chills, malaise and generalized muscular aches Diarrhea, usually of a watery type, may or may not be a cardinal symptom. Thus in an epidemic some individuals may have persistent vomiting without diarrhea while others suffer an almost intractable fecal incontinence Appearance of the vomitus or the stools is not remarkable and may differ from one outbreak to another Extremely high temperatures, respiratory or CNS signs are not usually observed Although onset is often very acute, the illness is of short duration, rarely lasting longer than 2 or 3 days, and, like its onset recovery is usually fast Fatalities are rare and confined to aged persons

Since repeated bacteriologic studies of these outbreaks have been fruitless, a viral cause of this syndrome has long been postulated, and this is supported by the isolation of several filterable agents from local epidemics Gordon et al (1949, 1956) found that volunteers who ingested filtrates of stool from patients with epidemic gastroenteritis rapidly developed severe watery diarrhea but little or no elevation of temperature The agent, designated Marcy, could be serially transmitted in human beings but has failed to infect human, rhesus or avian cells in tissue culture or suckling mice Human reinfection experiments indicated that an attack conferred immunity for at least 15 months A virus similar to the Marcy agent has been also found in Japan (Kojima et al, 1948) Another enteric virus, FS, capable of inducing a diarrhea but one in which fever is also a prominent symptom, was investigated by Jordan et al (1953), who demonstrated differences between the Marcy and the FS agents on the basis of their incubation period, clinical syndrome and the absence of cross-immunity Although the rapid spread of epidemic gastroenteritis suggests the respiratory tract as a portal of entry, attempts to transmit the

FS and the Marcy agents by the inhalation of infective throat washings have been unsuccessful. It is not unlikely that further study will disclose additional antigenic types of enteric viruses which are capable of causing transient gastroenteritis and fail to propagate in vitro.

A diagnosis of epidemic viral gastroenteritis is made on the basis of a clinical picture unlike that of bacterial gastroenteritis or dysentery, its infectiousness and rapid spread within a focus, and on negative bacteriologic findings. There is no specific therapy. Since it appears that entrance of the virus into the mouth results in infection, control measures involve strict attention to isolation and the general sanitary measures applicable to highly contagious diseases.

It is unknown whether or not epidemic viral gastroenteritis is related to the more severe epidemic diarrhea of the newborn in which pathogenic coliform bacteria are not involved. It is noteworthy that in this disease adult infection is rare, the course is more prolonged, and fatal cases are not uncommon. Search for an enterotropic virus in such outbreaks has yielded 2 agents. Light and Hodes (1943) produced a transmissible, bloody, mucoid diarrhea in calves by the intranasal administration of stool filtrates from sick infants Recovered calves could not be reinfected, nor were the stools of normal infants or calves able to produce the disease (The latter fact may be of significance in differentiating this virus from that described by Baker [1943] as causing diarrhea in calves.) Buddingh and Dodd (1944) investigated the etiology of nonfatal sporadic stomatitis and diarrhea of infants. A filterable virus was detected in throat-washings and stools which was capable of causing an iritis and conjunctivitis in the eye of the rabbit. It does not appear to be herpes simplex virus on the basis of the nonkeratitic nature and the short duration of the ocular lesions in rabbits, and

evidence that adults in close contact with the disease may become asymptomatic temporary carriers The relation of this and the other stool isolates described above to the better characterized enteroviruses remains obscure.

GENERALIZED SALIVARY GLAND VIRUS INFECTION

(SYNONYMS: Cytomegalic inclusion disease, submaxillary gland virus)

A virus disease of man and animals characterized by the presence of intracytoplasmic and intranuclear inclusion bodies in the cells of several organs, in many instances unassociated with clinical findings, was described over 50 years ago. Strains of the virus are species-specific, although the similarity of the morphologic changes they produce suggests that they are biologically closely related.

HISTORY

The first description of the inclusions typical of this disease in man was made by Jesionek and Kiolemenoglou (1904), and successful transmission using the guinea pig virus was reported in 1926 by Cole and Kuttner. The occurrence of salivary gland inclusions was subsequently observed in other species of rodents (Thompson, 1932) and monkeys (Cowdry and Scott, 1935). Smith successfully propagated salivary gland virus (SVG) from mice (1954) and from man (1956). Independently, Rowe et al. (1956) and Weller et al. (1957) recovered strains of SGV from human adenoids and liver biopsies, respectively, and the latter authors demonstrated its presence in the urine of in-

antigenically related to human strains.

CLINICAL PICTURE

The anatomic and clinical manifestations of SGV infection are varied In young infants the disease appears as a generalized blood dyscrasia associated with hepatomegaly and hepatic damage. Cerebral calcification and chorioretinitis have been reported (Weller et al, 1957). The disease is generally fatal at this age. When infection occurs in older children the clinical picture varies, depending on the organs involved. Severe diarrhea, hepatic and renal damage, pneumonia and cerebral lesions are commonly observed. It is frequently secondary to another illness and has been found with pertussis and fibrocystic disease of the pancreas (Smith and Vellios, 1950). Although diagnosed cases in adults have been rare, it appears probable that sub-

clinical infections are not infrequent The finding of virus in adenoidal tissue and in the urine of healthy persons, together with a high incidence of complement-fixing antibodies in adults (Rowe et al, 1956), suggests that SGV is a more widely distributed agent than was indicated by the number of diagnosed cases

Pathologic Picture

All strains of SGV virus, whether of rodent, simian or human origin, produce the same cytologic changes. The cells, usually in epithelial tissues, become greatly enlarged, and their nuclei contain prominent acidophilic or amphophilic bodies surrounded by a clear halo which [redacted] bounded by a sharply defined nuclear membrane. The cytoplasm may contain several small basophilic satellite bodies arranged around the periphery of the cell In fatal cases the lesions are most commonly found in the liver, the bile ducts, the renal tubules and the bronchial epithelium They are less frequent in the adrenals, the gastro-intestinal epithelium, the pancreas, the thyroid or the parathyroid. In experimentally infected guinea pigs, inclusion bodies are found only in mesodermal tissues Excellent colored photographs of SGV inclusions appear in an article by Cappel and McFarlane (1947)

Experimental Infection, Host Range

Experimental transmission of SGV disease has been obtained in mice, guinea pigs and rats, and the cultivation of rodent, simian and human strains is possible in tissue cultures of cells of the homologous species. In rodents infection is possible by a variety of routes of inoculation, although symptomatic disease does not always occur This appears to be due to widespread inapparent infection and resulting immunity, for intraperitoneal inoculation of SGV into young mice causes generalized disease in which there [redacted] severe visceral necrosis resulting in death in from 4 to 7 days (McCordock and Smith, 1936) Fatal meningitis in young rodents has been produced by intracerebral inoculation and in the case of guinea pigs by intrafetal injection of virus (Markham and Hudson, 1936).

Strains of SGV exhibit the same species specificity for tissue culture as for the host animal Human type SGV in tissue culture is neutralized by serum from infants with cytomegalic inclusion disease and occasionally by that of their mothers. Antibodies fixing complement in the presence of infected tissue culture fluid were found in a large proportion of adult human sera by Rowe et al (1956). These authors suggest that SGV may persist in human lymphatic tissue for many years.

The murine, guinea pig and human strains of SGV are destroyed by heating to 56° C for from 10 to 20 minutes, by exposure to 20 per cent ether for 2 hours, and all strains are inactive when kept at a pH below 5 0 (Hartley et al, 1957) Although SGV slowly loses infectivity at temperatures as low as −70° C., the murine strains appear to have been preserved for years in 50 per cent glycerol-saline

Diagnosis

Several methods are available for the diagnosis of this infection. Detection of typical inclusions in cells obtained by biopsy or in urinary sediments during life or in postmortem material is not difficult (Fetterman, 1952; Birdsong et al., 1956) Isolation of the virus from throat swabs, urine or tissue is best made in tissue cultures of human cells, but it should be borne in mind that fresh isolates usually grow slowly and may require careful examination over long incubation periods. The complement-fixation test employing antigens prepared from infected tissue culture has been useful as a diagnostic and epidemiologic tool (Rowe et al, 1956). These authors stress the high correlation between the isolation of SGV from children and the presence of complement-fixing antibody in their sera Neutralization tests can also be used for identification of the agent or the detection of specific antibody (Smith, 1956, Weller et al., 1957)

There is no known therapy for SGV infections

INCLUSION DISEASES OF POSSIBLE VIRUS ETIOLOGY

There are a number of human diseases wherein inclusion bodies are found after postmortem study which have been considered to be caused by one or more viruses.

Chronic, progressive encephalitis characterized by the presence of intranuclear and some-

FS and the Marcy agents by the inhalation of infective throat washings have been unsuccessful. It is not unlikely that further study will disclose additional antigenic types of enteric viruses which are capable of causing transient gastroenteritis and fail to propagate in vitro.

A diagnosis of epidemic viral gastroenteritis is made on the basis of a clinical picture unlike that of bacterial gastroenteritis or dysentery, its infectiousness and rapid spread within a focus, and on negative bacteriologic findings. There is no specific therapy. Since it appears that entrance of the virus into the mouth results in infection, control measures involve strict attention to isolation and the general sanitary measures applicable to highly contagious diseases

It is unknown whether or not epidemic viral gastroenteritis is related to the more severe epidemic diarrhea of the newborn in which pathogenic coliform bacteria are not involved It is noteworthy that in this disease adult infection is rare, the course is more prolonged, and fatal cases are not uncommon Search for an enterotropic virus in such outbreaks has yielded 2 agents. Light and Hodes (1943) produced a transmissible, bloody, mucoid diarrhea in calves by the intranasal administration of stool filtrates from sick infants Recovered calves could not be reinfected, nor were the stools of normal infants or calves able to produce the disease (The latter fact may be of significance in differentiating this virus from that described by Baker [1943] as causing diarrhea in calves) Buddingh and Dodd (1944) investigated the etiology of nonfatal sporadic stomatitis and diarrhea of infants. A filterable virus was detected in throat-washings and stools which was capable of causing an iritis and conjunctivitis in the eye of the rabbit. It does not appear to be herpes simplex virus on the basis of the nonkeratitic nature and the short duration of the ocular lesions in rabbits, and the fact that the sera of convalescent patients neutralize the virus but fail to neutralize herpes virus. Buddingh and Dodd also present evidence that adults in close contact with the disease may become asymptomatic temporary carriers. The relation of this and the other stool isolates described above to the better characterized enteroviruses remains obscure.

GENERALIZED SALIVARY GLAND VIRUS INFECTION

(Synonyms: Cytomegalic inclusion disease, submaxillary gland virus)

A virus disease of man and animals characterized by the presence of intracytoplasmic and intranuclear inclusion bodies in the cells of several organs, in many instances unassociated with clinical findings, was described over 50 years ago Strains of the virus are species-specific, although the similarity of the morphologic changes they produce suggests that they are biologically closely related

History

The first description of the inclusions typical of this disease in man was made by Jesionek and Kiolemenoglou (1904), and successful transmission using the guinea pig virus was reported in 1926 by Cole and Kuttner. The occurrence of salivary gland inclusions was subsequently observed in other species of rodents (Thompson, 1932) and monkeys (Cowdry and Scott, 1935) Smith successfully propagated salivary gland virus (SVG) from mice (1954) and from man (1956). Independently, Rowe et al. (1956) and Weller et al. (1957) recovered strains of SGV from human adenoids and liver biopsies, respectively, and the latter authors demonstrated its presence in the urine of infants with hepatosplenomegaly. Finally, Rowe (1958) has isolated SGV from the salivary gland of an African monkey. This virus is antigenically related to human strains.

Clinical Picture

The anatomic and clinical manifestations of SGV infection are varied. In young infants the disease appears as a generalized blood dyscrasia associated with hepatomegaly and hepatic damage. Cerebral calcification and chorioretinitis have been reported (Weller et al., 1957). The disease is generally fatal at [illegible]

and renal damage, pneumonia and cerebral lesions are commonly observed It is frequently secondary to another illness and has been found with pertussis and fibrocystic disease of the pancreas (Smith and Velios, 1950). Although diagnosed cases in adults have been rare, it appears probable that sub-

during the infection which usually precedes the polyneuritic attack Outbreaks of the disease do occur, chiefly in the colder months Persons of all ages may be attacked, but the morbidity is highest in those between 20 and 30 years of age; both sexes are equally affected Diagnosis is made on clinical findings, particularly a protein-cell dissociation in the cerebrospinal fluid There is no specific treatment or control measure

HEMORRHAGIC MENINGO-ENCEPHALITIS

(SYNONYMS: Strumpell's disease, acute epidemic leukoencephalitis)

Acute primary hemorrhagic meningo-encephalitis is a malady characterized by predominance of large or small hemorrhagic foci and perivascular demyelination throughout the CNS It is of interest that a hemorrhagic encephalitis occurs spontaneously in horses, acute epizootic leukoencephalitis, first described in 1901 Since diagnosis is based on clinical or pathologic findings and not on specific etiology, it is impossible to say whether or not the equine disease has any connection with that of man and whether or not all the reports of the human malady concern the same disease The human malady was first noted in 1881 In western Europe in 1891, cases occurred which were regarded as secondary to influenza Thereafter, sporadic cases were observed in Russia, Australia, England, United States and elsewhere (Hurst, 1941, Margulis et al, 1944) Margulis et al (1944) reported a study of 9 Russian cases conducted during 1939-1940 CNS tissue, blood or spinal fluid from 4 patients injected intracerebrally in mice yielded a virus which the investigators regarded as the causal agent of the malady

The onset is acute with fever, anorexia, dullness, or irritability for a day or two Then follows an acute and stormy syndrome of convulsions, delirium, nuchal rigidity, coma, and death within a week, or recovery after 7 to 20 days of illness Survivors who pass into a chronic stage show frequent exacerbations, varying paralyses, ataxia and nystagmus Pupillary or ocular palsies are rare Survivors may also exhibit permanent sequelae, such as athetoid movements, paralyses and psychoses The blood count reveals a moderate polymorphonuclear leukocytosis of 10,000 to 20,000 cells per cu mm, and the spinal fluid is clear, blood-tinged, under increased pressure, with moderate pleocytosis and increased protein The pathologic picture in the CNS is one of congestion of arterioles and capillaries, the walls of many vessels are broken and surrounding tissues are infiltrated with blood The vascular walls may be necrotic, and the vessels may be filled with thrombi There are concomitant gliosis, degeneration and necrosis of neurons, and inflammatory reaction in the gray and white matter, especially in the latter, with perivascular infiltration with round and plasma cells The distinctive feature is a perivascular demyelination The diagnosis should be made guardedly, since it is based at present only on clinical and pathologic pictures that are not markedly different from those occurring generally in the postinfection encephalitides (see below) The report on the causal agent (Margulis et al, 1944) needs confirmation

Persons of all ages can be attacked, but morbidity is highest in young people Mortality rates vary in different outbreaks from 15 to 70 per cent There is no specific treatment Control measures are unknown

DURAND'S DISEASE

(SYNONYM D virus infection)

In 1940, in Tunis, during a febrile illness, Durand isolated from his blood a virus, the properties of which were studied further by Findlay (1942), who was also attacked as a result of a laboratory infection In man, after experimental inoculation, there develops after from 2 to 4 days a local cutaneous lesion associated with viremia, fever, the presence of the virus in the cerebrospinal fluid, cough, vomiting and lethargy The symptoms persist for from 6 to 8 days, after which neutralizing and complement-fixing antibodies are found in the serum. The experimental animal of choice is the guinea pig, which is susceptible by intracerebral and peripheral inoculations of virus It exhibits fever, adenopathy, enlarged spleen and pneumonitis Monkeys,

times associated cytoplasmic inclusion bodies; mental deterioration and variable neurologic signs, reflecting widespread involvement of the CNS, has been first described (Malamud et al, 1950). This form can be distinguished from herpes simplex encephalitis and from the primary demyelinating diseases Such cases are found in children and adolescents who exhibit behavior disorders, dysphasia, tremor, apraxia, rigidity, choreiform movements and finally mental deterioration The malady endures for 2 to 6 months and is often fatal The blood shows a polymorphonuclear leukocytosis of 10,000 to 20,000 cells, and the cerebrospinal fluid, the paretic type of the Lange curve, but cells and protein are normal or slightly increased, also noted in an electroencephalographic reaction of periodic nature. A viral etiology is suspected, but no definite agent has as yet been isolated

A type of infantile pneumonia with pulmonary tissue inclusions was described by Goodpasture et al. (1939) Recent study by Chany et al (1958) suggests that this may be due to infection with an adenovirus Adams (1941) reported an outbreak of pneumonia in infants in which small intranuclear inclusions were observed in autopsy specimens The author suggests that distemper or measles virus, two agents which appear to be related, was the cause of this epidemic Additional investigation of the etiology of "inclusion diseases" would be profitable

INFECTIOUS POLYNEURITIS

(Synonyms Guillain-Barré disease, Landry's paralysis, encephalomyeloradiculitis, infectious neuronitis, acute polyneuritis with facial diplegia)

Infectious polyneuritis is characterized by neurologic signs referable to the peripheral spinal and cranial nerves and sometimes by involvement of the adrenals, the liver, the heart and the kidneys The outstanding features of the condition are a protein-cell dissociation observed in the cerebrospinal fluid, progression of the neurologic symptoms, tachycardia and gastro-intestinal disturbances It occurs after diseases associated with known bacterial toxins as in diphtheria and scarlet fever, after infections of unknown etiology involving the respiratory or the intestinal tracts, and occasionally without any recognized antecedent infection The malady usually endures for several weeks or rarely may last for 3 years or longer. Except in elderly people in whom the disease may be fatal, complete recovery is the rule. However, certain patients may show permanent weakness of one side of the face or other paretic and paralytic sequelae The mortality rate is about 20 per cent, and death often occurs within the first 2 weeks usually, as a result of paralysis of the intercostal muscles. Fatal cases in children may be wrongly diagnosed as poliomyelitis There is a mild polymorphonuclear leukocytosis of 10,000 to 15,000 cells, however, in the early stages of the disease, from 25 to 80 per cent of the white blood cells may be lymphocytes (Haymaker and Kernohan, 1949) Changes in the cerebrospinal fluid are characteristic; pressure is increased, cells may be normal in numbers or at times slightly increased, the amount of protein is usually greater than normal and may at times be as much as 800 mg per 100 cc. This increase of protein may persist for a long time

There are marked edema, congestion and focal inflammation of involved nerves and spinal roots Swelling and beading of the myelin sheaths occur as well as fragmentation, beading and dissolution of axons associated with marked proliferation of the neurilemmal cells No inflammation is found in the CNS, neuronophagia is absent. Neurons in the medulla, the cord and the ganglia may exhibit changes similar to those following section or damage of axons, viz, chromatolysis, eccentricity of nucleus, vacuolization of cytoplasm, and appearance of acidophilic bodies in the cytoplasm, a picture somewhat similar to that observed by Olitsky (1939) and others in avian encephalomyelitis. Focal degeneration and necrosis associated with infiltration by mononuclear cells may be present in the adrenals, the liver, the heart and the kidneys

Attempts to transmit the disease to lower animals have failed (Sabin and Aring, 1941) The etiology is as yet unknown, although it has been considered an infective agent, perhaps a virus The studies of Sabin and Aring (1941) led them to suspect that the disease was produced by a toxic substance developed

disturbances of the type seen in parkinsonism There also may be vegetative disturbances (sialorrhea, dacryorrhea and seborrhea) or psychotic signs.

During all stages of the disease, the blood count is of little diagnostic value The cerebrospinal fluid is usually clear and shows pleocytosis (lymphocytosis), normal or slightly increased amounts of sugar, and slight increase in protein It should be emphasized that the fluid is often completely normal

Pathologic Picture

Macroscopically, the CNS may show hyperemic areas in the meninges and hyperemia accompanied by small hemorrhages in the basal ganglia, the midbrain and the pons Microscopically, the lesions of von Economo's disease are as a rule slower in developing and are of a more chronic, productive type than are those of the established viral encephalitides They are usually found in the gray matter, particularly in the mesencephalon and the diencephalon (von Economo, 1917), and are (1) degenerative and (2) inflammatory and infiltrative The former are revealed by degeneration and necrosis of neurons associated with neuronophagia; the latter are evidenced by perivascular cuffings, focal glial cell proliferation and lymphocytic infiltrations, especially in the gray matter The perivascular reaction consists of accumulation of small and large mononuclear cells and plasma cells in the sheaths of the vessels and in the perivascular spaces Hemorrhages may be seen in limited areas of the cerebral cortex, the basal ganglia, the mid-brain and the pons Demyelination is not prominent, nor are lesions in the spinal cord marked

Etiology

The cause of the malady has not been discovered, even though its general aspect conforms with that of a viral infection

Diagnosis

No laboratory tests are available at present for specific diagnosis, the disease is recognized on clinical or pathologic grounds alone, and for that reason diagnoses are not always accurate

Treatment

There is no specific treatment available.

Epidemiology

The disease has been widespread throughout the world. It has a definite seasonal incidence, occurring chiefly in winter and early spring months Thus, its spread is probably not dependent on insects It has been suggested that the malady is spread by contact or droplet infection People of all ages may be attacked, but most patients are under 40 years of age, 25 per cent of cases occur in people from 10 to 20 years old The incidence is slightly higher in males than in females. The average mortality rate is 30 per cent. Residual symptoms occur in about 20 per cent of patients Methods for prevention of spread of this disease are unknown

POSTINFECTION (DEMYELINATING) ENCEPHALITIS

(Synonyms Acute demyelinating encephalomyelitis; acute disseminated encephalomyelitis; postvaccinal [or postmeasles, etc] encephalitis; acute perivascular myelinoclasis; acute primary myelinoclasis)

Introduction

Postinfection encephalitis is an acute affection of the CNS occasionally arising during convalescence from infectious diseases, especially those caused by viruses, or following vaccination against such diseases as smallpox and rabies, or developing spontaneously in certain instances without a prior history of disease or vaccination

History

A record of demyelination [illegible]

served following smallpox, it was noted in 1886 following measles, in 1887 following preventive inoculation against rabies, and in 1907 after vaccination against smallpox Outbreaks of postvaccinal encephalitis, which assumed epidemic proportions, occurred in England and Holland during 1922 and 1924, respectively In more recent times, cases of postinfection encephalitis have been observed following several other virus diseases, especially mumps, varicella and influenza

dogs, cats, merions, mice, hamsters and voles are also susceptible. The virus is found in their blood, organs and spinal fluid; on recovery, infected hosts develop neutralizing and complement-fixing antibodies. The virus multiplies in Maitland-type tissue cultures, and chick embryos succumb after introduction of virus into the yolk sac or chorio-allantois. The virus is about 65 mμ in diameter as determined by ultrafiltration through gradocol membranes. It is preserved by glycerolation, in the frozen state, or by lyophilization

ENCEPHALITIS LETHARGICA

(SYNONYMS: Von Economo's disease; type A encephalitis, epidemic encephalitis; sleepy or sleeping sickness)

INTRODUCTION

Encephalitis lethargica is a meningo-encephalomyelitis which is probably infectious and characterized by a wide variety of signs and symptoms in different individuals and in the same person at different stages of the malady; often it is associated with ophthalmoplegia and residual parkinsonism and occurs chiefly in spring and winter months None of the names given to this malady is satisfactory Certainly many of the patients are far from being sleepy, and now it is obvious that several encephalitic viruses cause epidemics

HISTORY

It may well be that the "sleeping sickness" associated with the influenza epidemic of 1712 and "nona" of about 60 years ago may have been von Economo's disease, but the first modern cases were probably observed in 1915 in Rumania Many patients were noted in France in 1916, but the first elaborate work on the disease as it occurred in Vienna in 1917 was by von Economo (1917). It appeared in 1918 in the United States in New York City, Iowa and West Virginia (Neal et al , 1942). Epidemics were reported from different parts of the world until 1926 when they apparently ceased and have not been [illegible] specific virus has as yet been recovered

CLINICAL PICTURE

The precise incubation period is unknown, but it is assumed to be from 4 to 15 days The clinical picture as described follows that given by Barker and revised by Rivers (1943). There is a marked diversity of signs and symptoms during the course of the affection so that any type of neurologic syndrome can be simulated. In general the symptom-complex is divided into 3 stages; the first exhibits many types, but two are well defined and common· (1) a somnolent-opthalmoplegic syndrome, and (2) an irritative, hyperkinetic complex, either choreiform or myoclonic The somnolent-ophthalmoplegic type is characterized by a brief initial stage with fever, meningeal irriation, drowsiness and ocular paralyses. Other symptoms may develop, such as rigidity, paralyses of other members and psychotic disturbances. The hyperkinetic type is initiated by fever and excitement which is followed by choreiform movements or myoclonic contractions Other types seen at times during the first stage are the psychotic, with patients exhibiting a variety of signs ranging from those found in simple mental impairment to those seen in conditions simulating general paresis or schizophrenia; the poliomyelitic type with lower motor neuron paralyses, the type with involvement of posterior root ganglia; tabetic type with ataxia, an epileptomaniacal type; cataleptic type, amyostatic-akinetic form (apathy, rigidity, akinesia, amimia, slow motion and tremor); and finally, the fulminating type from which the patient succumbs within a few hours after the onset.

Of importance is the fact that during an epidemic a large number of patients may show aberrant forms and inapparent disease. In the latter case, the first suspicion of an encounter with the malady is the appearance of definite parkinsonism.

The second stage (pseudopsychoneurotic) may persist for months or years and is characterized by subjective symptoms such as headache, insomnia, irritability, dizziness and fatigue. Often objective signs of CNS lesions may be lacking.

The third stage (chronic) at times immediately follows the first and consists of motor

Louis encephalitis, the lesions are mostly in the gray matter, and neuronal damage and death are a prominent part of the picture Hurst (1944) regards the changes as nonspecific, i.e., as reactions to different agents. According to Roizin et al., (1946) and others, the lesions are in many respects similar to *those observed in other demyelinating maladies*, for example, multiple sclerosis

Etiology

Postinfection encephalitis has not been transmitted to experimental animals. There has been much speculation concerning the etiology of this demyelinating process, and the matter has been discussed at length by Hurst (1944, 1953) and Ferraro (1944)

Among the theories advanced are: (1) the infection theory, which implies that the disease is caused through action on the CNS by the virus causing the primary disease e g measles, or by the activation of a latent virus already present in the host At the present time it is safe to say that no one has definitely shown the direct action of a virus to be the cause of postinfection encephalitis Therefore, caution must be used in the interpretation of the role of the occasional virus reported to have been recovered from patients with this disease

(2) Another theory relates to toxins or poisons as the etiologic agents which are assumed to be developed during the course of the primary viral attack In this group of agents belong poisons that induce cerebral anoxia (Ferraro, 1944, Hurst, 1944) This theory was advanced because of the fact that lesions produced in the CNS by CO, KCN and tetanus toxin resemble those of postinfection encephalitis

(3) The enzyme theory assumes that myelin-destroying agents are produced in the patient or that those already present are activated by the viral infection; this theory has at present little support

(4) The theory relating to vascular thrombi has been actively advanced, especially by Putnam (1941) and his colleagues. Encephalitis and plaques of demyelination have been produced experimentally by the intravenous injection of oil or various blood coagulants into animals.

(5) The idea that phenomena of immunity or allergy play a role in the causation of postinfection encephalitis arose as the result of experimental investigations. Demyelination and inflammation of the CNS of monkeys was produced by the intramuscular injections of emulsions of normal rabbit brain tissue (Rivers et al., 1933). This work has been expanded by Morgan (1949) and by Kabat et al (1947) who injected intramuscularly into monkeys a mixture of normal monkey-brain tissue, dead tubercle bacilli and oil, and by others who successfully used rabbits, guinea pigs and mice (Olitsky and Yager, 1949) The view that the pathologic processes in postinfection encephalitis are the expression of phenomena of allergy or immunity receives support from the fact that encephalitis sometimes follows the use of immune sera or vaccines or develops in the course of antirabic treatment (Rivers 1932, Findlay, 1940; Putnam 1941, Ferraro, 1944, Hurst, 1953).

Diagnosis

Diagnosis is ordinarily made from clinical findings and a history of convalescence from a viral infection or of having been vaccinated recently Postinfection encephalitis should be distinguished from an encephalitis that may occasionally arise during the course of a viral disease for example, measles and mumps. In the latter case, the encephalitis may be caused by the virus responsible for the primary disease and the pathologic picture is wholly different from that seen in the demyelinating postinfection encephalitides Therefore, the diagnosis is difficult, and confirmation can be had only by finding the characteristic perivascular demyelination in the CNS at necropsy The disease should also be differentiated from

other encephalopathies listed by Roizin et al (1946), who believe that from a histopathologic point of view all types of demyelinating diseases, including postinfection encephalitis and acute hemorrhagic meningoencephalitis (see above), belong to one group of primary demyelinating processes, and that differences among them can be ascribed to age of the patient, duration of the affection, distribution of lesions, and degrees of host resistance

Clinical Picture

The clinical picture seen in encephalitis that develops during convalescence from viral infections depends on the type, the extent and *the location of the lesions in the CNS*. In general, it is encephalitic, myelitic, or encephalomyelitic. The encephalitic form is commonly seen following vaccination against smallpox, the myelitic type usually occurs after antirabic treatment, and both kinds are seen with equal frequency after variola. Most cases of postinfection encephalitis follow measles and vaccination against smallpox, and the picture seen under these conditions is described in detail.

Postvaccinal encephalitis usually develops abruptly from 2 to 24 days (average 10 days) after vaccination. In the encephalitic type, fever, headache, vomiting and drowsiness occur, which may be followed by photophobia, delirium, convulsions, trismus, paralyses, transient muscular weakness, in-co-ordination, ataxia, and a variety of disturbances of deep and superficial reflexes. In the myelitic type, paralyses and sensory disturbances are usually present. The course of the disease is fairly rapid and terminates in recovery within 7 to 14 days, or in the death of from 37 to 58 per cent of the patients. In most instances recovery is complete; this is a striking feature of postvaccinal encephalitis when compared with *postmeasles encephalitis, which* not infrequently is followed by sequelae.

The first indication of the development of postmeasles encephalitis is usually noted after the rash has disappeared, 4 to 6 days after defervescence. In infants, the first sign of CNS involvement may be convulsions. In older children, the disease is ushered in by drowsiness, stupor, meningismus, and con*vulsions at times. Muscular twitchings, rigid*ity, choreiform movements, ataxia, spastic paralyses, aphasia and psychic disturbances may be observed. Of particular note is the occurrence of cerebellar ataxia and, in certain instances, flaccid paralyses. Infants and children usually recover, but sequelae, such as spastic paralysis, tremors, choreic or athetoid movements, and psychic derangements may *occur.*

Encephalitis rarely follows German measles but, when it does, the clinical picture is not essentially different from that of postvaccinal encephalitis. Such is also true of the rare cases of encephalitis following dengue, smallpox and yellow fever. The encephalitis *that follows varicella is more common and is* somewhat similar to postmeasles encephalitis, i.e., cerebellar forms are prominent. Postmumps encephalitis must be differentiated from mumps meningitis and mumps meningoencephalitis. The former disease is not caused by the direct action of mumps virus, and perivascular demyelination is prominent in the pathologic picture, while the latter condi*tions are due to the direct action of mumps* virus on CNS tissue, and perivascular demyelination is not a part of the pathologic changes observed. The symptomatology and the course of the demyelinating encephalitis, which follows antirabies vaccination and bacterial infections or which arise spontaneously, are similar in most respects to the postinfection encephalitis that follows viral infections.

The cerebrospinal fluid of patients with postinfection encephalitis is clear, under increased pressure, free from infective agents, contains a normal amount of sugar and a slightly increased amount of protein and usually reveals a lymphocytic pleocytosis which may be as high as 300 cells.

Pathologic Picture

[illegible]

vascular lesions and thrombus formation which may be seen most frequently in small vessels. Hemorrhages and perivascular infiltration with lymphocytes and glial cells are found; the glial cells exhibit proliferation and active phagocytosis of fat and myelin material. A gliosis is also found diffusely scattered throughout the CNS. Degeneration and necrosis of neurons are not marked. One or another of the lesions may predominate or may be absent in any single case (Findlay, 1940). Therefore, the main features are the peri*vascular demyelination in the gray and white* matter of the brain and the cord, which may occur with or without hemorrhage, and only a slight amount of neuronal degeneration and necrosis. Rivers (1932) holds that the pathologic changes in postinfection encephalitis are not those usually produced by the direct action of a virus on the CNS where, as in St.

following World War I the disease ceased to be recognized, but it reappeared in epidemic form on the eastern European front in World War II, particularly in Jugoslavia and the Ukraine. Body lice collected in Mexico City have been found to be infected by rickettsia resembling *R. quintana* (see below), and inoculation of volunteers with louse feces produced a disease in them resembling trench fever (Varela et al, 1954).

Trench fever (Swift, 1919-1920) was characterized by sudden onset, chills, headache, dizziness, postorbital pain, nystagmus, injection of conjunctivae, severe pains in legs and back, relapsing fever, tachycardia, large spleen, and several crops of erythematous macules or papules on the chest, the abdomen and the back About one half of the patients had only one bout of fever, while the others had from 3 to 8 relapses. The incubation period in most of the human volunteers ranged from 14 to 30 days Most patients recovered in 5 or 6 weeks, others were sick for several months and in some instances for a year or two White blood cell counts were not characteristic and varied from 4000 to 27,000 per cu mm The disease was never fatal, and what is known concerning the pathologic picture was determined from biopsies of skin which showed inflammation around the small blood vessels without involvement of the walls of the vessels as is the case in typhus fever and Rocky Mountain spotted fever.

Several commissions (Strong et al, 1918) were appointed to investigate trench fever, and the combined results showed that none of the usual laboratory animals was susceptible to the disease By use of human volunteers, it was demonstrated that the etiologic agent was present in blood, sputum and urine. In 3 of 5 experiments the agent was passed with difficulty through Chamberland L filters It resisted a temperature of 60° C moist heat for 30 minutes but was inactivated by a temperature of 70° C. moist heat for a similar length of time. The body louse, *Pediculus humanus*, var. *corporis*, was shown to be a vector; it became capable of transmitting the disease 5 to 10 days after having fed upon a patient The etiologic agent was demonstrated in the lice and in their feces Since the disease was transmitted by bites, it is obvious that the infectious agent was either in the saliva or in the material regurgitated during the process of biting. Human volunteers were also infected by bringing the causative agent in contact with abraded skin. Once a louse had been infected, it excreted the active agent for the remainder of its life, which was not shortened as a result of the infection. The agent was not transmitted to larvae through eggs. Small bodies similar to rickettsiae were found in the guts of infected lice and in their feces and were not present in the absence of infection Many observations of this kind induced most investigators to place trench fever in the rickettsial group of diseases The etiologic agent was picked up from patients by lice during the first few weeks of the disease. A patient who had completely recovered was no longer a source of danger. Some patients had a chronic infection, and in several instances lice became infected by biting such patients as late as the 300th and the 443rd day after onset of illness The immunity that developed was considered to endure for only a short time, viz, several months

Mooser and his associates (Mooser et al., 1948, 1949) who investigated trench fever as it occurred in World War II, appear to have substantiated the rickettsial nature of the disease. They were able to isolate a strain of rickettsia, designated as *R. quintana*, by feeding lice on a trench fever patient in Jugoslavia Although attempts to infect mice, rats, guinea pigs, hamsters, embryonated eggs or tissue cultures with the agent were fruitless, lesions could be produced by the inoculation of infected lice intracutaneously or into the anterior optic chamber of rabbits When louse feces containing *R. quintana* were rubbed into the scarified skin of human volunteers a disease identical with trench fever resulted Mooser and his associates prepared an attenuated skin-test antigen from saline suspensions of desiccated infected intestinal tracts of lice Intradermal inoculation of a nonimmune person with this material resulted in a vesicle at the site which developed into an escharlike scab and persisted for many weeks. The lesion was frequently accompanied by a rickettsemia and clinical trench fever. Persons recovered from trench fever developed only a transient papule Subsequently, Mooser and Weyer (1953) were able to produce a subclinical infection in rhesus monkeys inoculated intravenously with a suspension of louse in-

to the causal agent. Therefore, the differences may be apparent, not real (Ferraro, 1944; Hurst, 1944, 1953).

Treatment

There is no specific treatment. On the hypothesis that encephalomyelitis may arise on a basis of hypersensitivity, ACTH or cortisone has been tested in therapy (Selling and Meilman, 1955) Prompt improvement has been observed in some cases.

Epidemiology

The occurrence of postinfection encephalitis has no relationship to the severity of the primary viral attack or to the immediate reactions after vaccination against smallpox or rabies In postvaccinal encephalitis, moreover, there is no relationship to the strain of vaccine virus used Encephalitis rarely follows the second or subsequent vaccinations against smallpox; there is no relation between morbidity and the amount of vaccine virus used or

fants or adults, e g , the largest number of cases occur in children from 2 to 14 years of age In England 93 cases of postvaccinal encephalitis were observed between 1922 and 1928, in Holland 150 between 1924 and 1928; in the United States, 71 between 1923 and 1932. Up to 1943, more than 200 cases of postmeasles encephalitis were recorded

the material used, 1 of 17,020 persons receiving antirabic vaccination with heat-inactivated virus exhibited paralysis (Casals, 1945), while in China, 5 of 201 persons who were vaccinated developed neurologic syndromes, and two of them died The general

Attention has been directed to the harmful effects on the CNS of the unborn young of maternal virus infections which occur in the early months *of pregnancy; especially,* in the case of rubella during the first 2 or 3 months It is assumed that the fetal tissues, because they are embryonic, are more susceptible. Among other viral infections implicated are rubeola, varicella, vaccinia and mumps, poliomyelitis and equine encephalomyelitis. The neurologic and mental signs shown in infants are optic atrophy, strabismus, deaf-mutism,

normal children. An interesting phase of this problem has been brought into light by Japanese and American observers (Burns, 1950). A congenital infection in swine with Japanese B encephalitis virus is described which results in stillbirth or death during the neonatal period; marked lesions of encephalitis are noted in the young, but the sows present no or negligible evidence of infection.

With respect to vaccination of pregnant women against smallpox, it would appear that risk of fetal complications exists especially if vaccination is performed in the first trimester when 24 per cent lost their fetuses as against 3 and 2 per cent loss, respectively, in the 2nd and the 3rd periods (MacArthur, 1952)

Control Measures

Since the cause of postinfection encephalitis *has not been definitely established, it is difficult* to say much about control measures. Vaccines made from nervous tissues, and particularly those containing nervous tissue to which killed tubercle bacilli and oil have been added, should be used with great care (Rivers et al., 1933; Morgan, 1947; Kabat et al, 1947) Since infants are least often attacked by postvaccinal encephalitis, primary vaccina*tion against smallpox should be performed at* the age of about 6 months and revaccination on entering school.

TRENCH FEVER

(Synonyms: Wolhynian fever, His-Werner disease, shin fever, shank fever, 5-day fever)

Trench fever was unknown until 1915, but during World War I it involved at least 1,000,000 men With *the exception of influenza,* it caused the loss of more man-days in the armed forces than did any other sickness. It is believed to have come from Russia and is known to have occurred in England, France, Flanders, Salonica, Mesopotamia, Italy, Germany and Austria In the years immediately

following World War I the disease ceased to be recognized, but it reappeared in epidemic form on the eastern European front in World War II, particularly in Jugoslavia and the Ukraine. Body lice collected in Mexico City have been found to be infected by rickettsia resembling *R. quintana* (see below), and inoculation of volunteers with louse feces produced a disease in them resembling trench fever (Varela et al., 1954).

Trench fever (Swift, 1919-1920) was characterized by sudden onset, chills, headache, dizziness, postorbital pain, nystagmus, injection of conjunctivae, severe pains in legs and back, relapsing fever, tachycardia, large spleen, and several crops of erythematous macules or papules on the chest, the abdomen and the back. About one half of the patients had only one bout of fever, while the others had from 3 to 8 relapses. The incubation period in most of the human volunteers ranged from 14 to 30 days. Most patients recovered in 5 or 6 weeks, others were sick for several months and in some instances for a year or two. White blood cell counts were not characteristic and varied from 4000 to 27,000 per cu mm. The disease was never fatal, and what is known concerning the pathologic picture was determined from biopsies of skin which showed inflammation around the small blood vessels without involvement of the walls of the vessels as is the case in typhus fever and Rocky Mountain spotted fever.

Several commissions (Strong et al., 1918) were appointed to investigate trench fever, and the combined results showed that none of the usual laboratory animals was susceptible to the disease. By use of human volunteers, it was demonstrated that the etiologic agent was present in blood, sputum and urine. In 3 of 5 experiments the agent was passed with difficulty through Chamberland L filters. It resisted a temperature of 60° C moist heat for 30 minutes but was inactivated by a temperature of 70° C. moist heat for a similar length of time. The body louse, *Pediculus humanus*, var. *corporis*, was shown to be a vector, it became capable of transmitting the disease 5 to 10 days after having fed upon a patient. The etiologic agent was demonstrated in the lice and in their feces. Since the disease was transmitted by bites, it is obvious that the infectious agent was either in the saliva or in the material regurgitated during the process of biting. Human volunteers were also infected by bringing the causative agent in contact with abraded skin. Once a louse had been infected, it excreted the active agent for the remainder of its life, which was not shortened as a result of the infection. The

induced most investigators to place trench fever in the rickettsial group of diseases. The etiologic agent was picked up from patients by lice during the first few weeks of the disease. A patient who had completely recovered was no longer a source of danger. Some patients had a chronic infection, and in several instances lice became infected by *biting such patients as late as the 300th and* the 443rd day after onset of illness. The immunity that developed was considered to endure for only a short time, viz., several months.

Mooser and his associates (Mooser et al., *1948, 1949) who investigated trench fever as* it occurred in World War II, appear to have substantiated the rickettsial nature of the disease. They were able to isolate a strain of rickettsia, designated as *R. quintana*, by feeding lice on a trench fever patient in Jugoslavia. Although attempts to infect mice, rats, guinea pigs, hamsters, embryonated eggs or tissue cultures with the agent were fruitless, lesions could be produced by the inoculation of infected lice intracutaneously or into the anterior optic chamber of rabbits. When louse *feces containing R. quintana were rubbed* into the scarified skin of human volunteers a disease identical with trench fever resulted. Mooser and his associates prepared an attenuated skin-test antigen from saline suspensions of desiccated infected intestinal *tracts of lice. Intradermal inoculation of a* nonimmune person with this material resulted in a vesicle at the site which developed into an escharlike scab and persisted for many weeks. The lesion was frequently accompanied by a rickettsemia and clinical trench fever. *Persons recovered from trench fever developed* only a transient papule. Subsequently, Mooser and Weyer (1953) were able to produce a subclinical infection in rhesus monkeys inoculated intravenously with a suspension of louse in-

testines containing *R. quintana*. By intrarectal inoculation of lice it was possible to establish that a prolonged rickettsemia developed, and Mooser and Weyer conclude that the rhesus monkey is a satisfactory animal for the experimental study of this highly fastidious agent.

Although as yet untried in trench fever, the present armamentarium of insecticides, e g, DDT, for louse control, together with the effectiveness of several antibiotics in rickettsial diseases, provide promising methods for control and treatment; thus, it appears unlikely that the disease will appear again in serious epidemics
